ABSTRACT

The deadline scheduling problem in project management is a NP-hard problem with major relevance in software engineering and scheduling of activities. In this article, we introduce an efficient parallel evolutionary algorithm applied to solve that problem, engineered to compute accurate solutions in reduced execution times. Specific evolutionary operators are proposed to allow solving realistic problem instances, and a master-slave parallel strategy is applied to further improve the computational efficiency and the results quality. The experimental analysis performed on a set standard problem instances shows that accurate solutions are computed. The comparative evaluation demonstrates that the proposed parallel evolutionary algorithm is able to outperform one of the best well-known deterministic techniques for the problem in reduced execution times, especially when facing instances with tight deadline constraints.

Main areas: Metaheurísticas, Gestão de projetos.

1. Introduction

Project management involves planning and organizing a set of activities in order to generate a product or offer a service in the best possible way (Nicholas and Steyn 2011). In order to shorten the project duration, some activities can be performed faster by employing additional resources, increasing the cost of the entire project. Considering that each activity can be performed by using a set of alternative *modes*, each one defined by a time-cost pair, a key problem to enable the best project performance consists in finding a schedule that assigns modes to activities, providing a good tradeoff between the duration and cost for each activity. In this article, we tackle the scheduling problem known as Deadline Problem in Project Management (DPPM), which accounts for both precedence between activities and deadline for its execution. In the related literature, the problem is also known as the Discrete Time/Cost Trade-off Problem (DTCTP).

Traditional scheduling problems are NP-hard (Garey and Johnson 1979), thus classic exact methods are only useful for solving problem instances of reduced size. Heuristics and metaheuristics are promising methods for solving scheduling problems, since they are able to get efficient solutions in reasonable time, even for large problem instances. Evolutionary algorithms (EAs) have emerged as flexible and robust metaheuristic methods for solving this kind of complex problems, achieving the high level of accuracy and efficiency also shown in many other application areas (Bäck et al. 1997). Parallel implementations have been proposed to improve both the computational efficiency and search quality of EAs (Alba 2005).

The main contributions of this article are: i) to introduce a highly efficient parallel EA to solve the DPPM, designed to solve realistic instances in reduced execution times, and ii) to efficiently compute accurate schedules, outperforming previous results in literature, for a set of problem instances with tight deadline constraints. Overall, the proposed parallel EA was able to compute **12 new best solutions** for the set of 36 problem instances tackled.

The manuscript is structured as follows. Section 2 describes the paradigm of evolutionary computation and parallel EAs. The DPPM formulation is introduced in Section 3. Section 4 reviews previous works applied to solve the DPPM and problem variants. The features of the parallel EA used in the study are described in Section 5. The experimental analysis and the discussion of the results are presented in Section 6, while the conclusions and main lines for future work are formulated in Section 7.

2. Evolutionary algorithms and parallel implementations

EAs are non-deterministic methods that emulate the evolutionary process of species in nature, in order to solve optimization, search, and machine learning problems (Bäck et al. 1997). In the last twenty-five years, EAs have been successfully applied for solving optimization problems underlying many real applications of high complexity.

An EA is an iterative technique (each iteration is called a *generation*) that applies stochastic operators on a pool of individuals (the population *P*) in order to improve their *fitness*, which is a measure related to the objective function. Every individual in the population is the encoded version of a solution for the problem. The initial population is generated by a random method or by using a specific heuristic for the problem. An evaluation function associates a fitness value to every individual, indicating its suitability to the problem. Iteratively, the probabilistic application of *variation operators* like the *recombination* of parts from two individuals or random changes (*mutations*) are guided by a selection-of-the-best technique to tentative solutions of higher quality. The stopping criterion usually involves a fixed number of generations or execution time, a quality threshold on the best fitness value, or the detection of a stagnation situation. Specific policies are used to select the groups of individuals to recombine (the *selection* method) and to determine which new individuals are inserted in the population in each new generation. The EA returns the best solution ever found, taking into account the fitness function.

Parallel implementations are used to improve the efficiency of EAs. By using several computing elements, parallel EAs allow reaching high quality results in a reasonable execution time even for hard-to-solve optimization problems. Three main paradigms have been proposed in the related literature to design parallel EAs, regarding the criterion used for the organization of the population (Alba and Tomassini2002). In this work, we have applied the *master-slave* model to design the proposed parallel EA.

The master-slave model follows a functional decomposition of the evolutionary search. A master-slave parallel EA is organized in a hierarchic structure: a master process guides the search, while it controls a group of slave processes which perform the fitness function evaluation and/or the application of the variation operators (when they require large computing times) over different candidate solutions in parallel.

3. Deadline Problem in Project Management

The DPPM formulation considers the following elements:

- A set of activities $A = \{a_1, a_2, ..., a_N\}$ with starting times S_i . Some activities may require the completion of some other activities before they begin, so a *precedence function P* is defined, where P_i is the set of immediate predecessors of activity a_i .
- A set of execution modes $M_i = \{m_{i1}, m_{i2}, \dots, m_{iR_i}\}$ is defined for each activity a_i , where each activity must be assigned to exactly one mode.
- For each activity a_i and each mode m_{ik} the time/cost pair (t_{ik}, c_{ik}) is defined, where t_{ik} is the duration and c_{ik} is the cost. For any two modes m_{ik_1} and m_{ik_2} of a given activity a_i , $t_{ik_1} < t_{ik_2}$ implies $c_{ik_1} > c_{ik_2}$, which means that in order to speed up the time of a given activity additional resources are needed, i.e. higher costs are demanded. In addition, $k_1 > k_2$ implies $t_{ik_1} > t_{ik_2}$ for all activities a_i , that is, the activity modes are ordered by decreasing order of duration.
- A deadline *T* for the project duration is established.

The goal of the DPPM is to find a *schedule*, i.e. a function $f: M^R \to A^N$ that assigns modes to the activities, which minimizes the total cost while fulfilling the precedence constraints and subject to that the entire project duration cannot exceed the deadline *T*.

For the DPPM mathematical formulation, let consider two dummy activities, a_0 which precedes all those real activities with no predecessors, and a_{N+1} , which is performed after all activities having no successors are finished (thus, S_{N+1} is the entire project duration), and the binary decision variables y_{ik} , whose values are given by Eq. 1.

$$y_{ik} = \begin{cases} 1, & \text{if activity } a_i \text{ is assigned to mode } m_{ik} \\ 0, & \text{otherwise} \end{cases}$$
(1)

So, the DPPM formulation as an optimization problem is presented in Eq. 2.

Minimize
$$\sum_{i=1}^{N} \sum_{k=1}^{R_i} c_{ik} \cdot y_{ik}$$
(2.1)

subject to
$$\sum$$

$$= 1, i = 1 \dots N \tag{2.2}$$

$$\sum_{k=1}^{N} y_{ik} = 1, i = 1 \dots N$$

$$S_i \ge S_j + \sum_{k=1}^{R_j} t_{jk} \cdot y_{jk}, \quad j \in P_i, i = 1 \dots N + 1$$
(2.2)
(2.4)

$$S_{N+1} \le I$$
 (2.4)
 $S_i > 0, i = 1 \dots N + 1$ (2.5)

$$y_{ik} \in \{0,1\}, i = 1 \dots N + 1, k = 1 \dots R_i$$
 (2.6)

The DPPM objective is the minimization of the total cost (2.1). The constraints of the problem are: each activity must be assigned to exactly one mode (2.2); an activity cannot start before all its immediate predecessors are completed (2.3); the entire project duration cannot exceed the deadline T (2.4); the starting time of the activities must be nonnegative (2.5); and the values of y_{ik} are binary (2.6).

4. Related work: heuristics and metaheuristics for the DPPM

This subsection presents a review of previous works that have proposed applying heuristics and metaheuristics to the DPPM and related variants of the problem.

Pioneering works on scheduling proved that for linear time/cost functions, the DPPM can be solved by traditional methods such as Maximum Flow or Cut Search algorithms. Dunne et al. (1997) showed that the DTCTP is NP-hard in the strong sense, but some special structures like pure parallel and pure series are solvable in polynomial times.

Demeulemeester et al. (1998) solved the Time/Cost Curve Problem by applying a horizon-varying approach using iterative solutions of the DPPM, computed with a Branch and Bound (BAB) algorithm using Linear Relaxation based lower bounds (LB). The proposed approach solved small-sized instances up to 30 activities and four modes easily, but failed to solve most of the tackled instances with 40 activities. Deineko et al. (2001) proved that there cannot exist a polynomial time approximation algorithm with a performance guarantee better than 3/2 for any versions of the DTCTP.

Akkan et al. (2005) computed LB for the DPPM using column generation techniques based on a network decomposition approach. The proposed techniques were also applied to construct feasible solutions. The experimental analysis revealed the satisfactory behavior of the algorithm, which obtained solutions with average gap less than 7% in only 6 seconds.

Hafizoglu and Azizoglu (2010) studied algorithms based on linear programming relaxation to solve the DPPM. They defined two LBs on the optimal total cost, namely Naive Bound and LPR-Based LB, which are used in their BAB algorithm to define the branching strategy and to eliminate non-promising partial solutions. BAB solved instances with up to 150 activities and 10 modes in reasonable execution times, showing a satisfactory behavior for loose deadline time constraints. However, when faced with tighter constraints, the execution time of BAB increased considerably, reaching an hour of computing time. Up to our knowledge, the BAB algorithm is one of the best method for solving the DPPM, although it demands a large computing time for instances with tight deadlines.

Anagnostopoulos et al. (2010) developed five variants of a simulated annealing (SA) algorithm for the DPPM, using different parametrizations. The SAs achieve feasible solutions in a few seconds, and solved large-sized instances up to 300 activities with 4 modes. However, the quality of the computed solutions is only evaluated with estimations of the global optimum within a certain confidence interval.

Hazir et al. (2010) proposed an exact algorithm to solve the time minimization version of the DTCTP by a decomposition strategy. A *master problem* solves a relaxed DTCTP generating a LB for minimization and trial values for the integer variables to be used as fixed values in the *subproblem*. Instances with 85 to 136 activities, 2 to 10 modes, and tight deadline constraints were solved. The results show that 74% of the instances are solved exactly in 10 minutes, 96% in an hour, and all of them are solved in 90 minutes. Up to our knowledge, this is the best method for the time minimization DTCTP with tight deadlines.

Zhang et al. (2010) extended the DTCTP by considering renewable and non renewable resource-constrains simultaneously. A genetic algorithm was implemented for this problem, which is able to solve an instance with two renewable and two nonrenewable resources and with up to 30 activities and three modes. The computation experiments show that the algorithm solved these instances in no more than four seconds.

Recently, Fallah-Mehdipour et al. (2012) included a new parameter, the quality of the project, to previously considered time and cost parameters. Two multiobjective EAs (NSGA-II and MOPSO) are used to solve the proposed problem. The experimental analysis solved two instances with two objectives and 18 activities, and three objectives and 7 activities, respectively. The results show that both multiobjective EAs are able to achieve feasible solutions, but no computing times are reported.

Up to our knowledge, there are no antecedents of previous works applying parallel metaheuristic to solve the DPPM/DTCTP.

Summarizing, the analysis of the related works shows that solving DPPM/DTCTP instances with tight deadline constraints in reduced execution times is a hard task. For this kind of instances, the best existing approaches demands more than one hour of execution time. Thus, there is still room to contribute in this line of research, by developing efficient and accurate methods to solve the DPPM/DTCTP, able to handle the increasing complexity of realistic instances with tight constraints in reduced execution times.

5. An efficient parallel EA for the DPPM

This section presents the main features of the proposed parallel EA for the DPPM.

5.1. The GAlib library

The algorithm was implemented on GAlib, a library for EAs developed in C/C++ using the object oriented paradigm (Wall 1996). The library includes tools to implement EAs and offers the possibility of developing user-defined representations and operators. Several modifications were needed in order to provide support for the master-slave model applied to the proposed EA, including: i) implementing the thread creation, management, and synchronization, ii) implementing a thread-safe variant for the pseudorandom number generator, and iii) applying mutual exclusion sections for the selection operator, population, and statistical variables.

5.2. Features of the proposed EA

This subsection presents the main features of the proposed parallel EA, designed with two main goals: computing accurate DPPM solutions in reduced time and providing a good exploration pattern by using ad-hoc variation operators.

Solution encoding. A non-traditional encoding is defined to represent solutions, taking into account the precedence relations between activities and the different modes in which each activity can be performed. Each individual in the population is encoded as an array $I = (I_0^0, I_1^a, ..., I_k^k, ..., I_N^b, I_{N+1}^0)$ where I_i represents the activity a_i , and I_i^k denotes the activity a_i in mode m_{ik} . The execution order of activities is from left to right: all of the predecessors of activity I_i are located before—i.e. at the left—of I_i . *Fitness function*. Let *S* be a solution, represented by $(I_0^0, I_1^{k_1}, ..., I_k^{k_i}, ..., I_N^{k_N}, I_{N+1}^0)$.

Fitness function. Let *S* be a solution, represented by $(I_0^0, I_1^{k_1}, ..., I_i^{k_i}, ..., I_N^{k_N}, I_{N+1}^0)$. The fitness function is given by Eq. 3, where *C* is the maximum cost of the project, i.e. the sum of all activity costs assuming that all activities are in the costliest mode.

$$fitness(S) = C - \sum_{i=1}^{N} cost(I_i^{k_i})$$
(3)

Feasibility check and repair mechanism. The proposed operators never violate the precedence constrains, but they can generate non-feasible solutions that do not fulfill the deadline constraints. Thus, a feasibility check/repair method is applied to correct non-feasible solutions. The total time of the project cannot exceed the deadline *T*. Therefore, any individual $(I_0^0, I_1^{k_1}, \ldots, I_i^{k_i}, \ldots, I_N^{k_N}, I_{N+1}^0)$ must fulfill $time(I_1^{k_1}) + \cdots + time(I_i^{k_i}) + \cdots + time(I_i^{k_N}) < T$. When this condition is not verified, the feasibility repair mechanism works by randomly selecting an activity and changing its mode in order to demand a shorter execution time. This procedure is iteratively applied until the deadline constraint is met.

Initialization. An initial population of feasible solutions is generated by applying an ad-hoc randomized construction operator. Starting from $I = (I_0^0, \emptyset, ..., \emptyset, ..., \emptyset)$, a new activity I_i in mode m_{ik} is randomly selected. If all the predecessors of activity I_i have been inserted in the solution, then I_i^k is inserted in the first available empty location. Otherwise, another activity is selected. When the whole schedule has been constructed, the feasibility check/repair mechanism is applied in order to meet the deadline constraints.

Selection. The proportional selection method is used. An individual I is selected to recombine/mutate with probability p_s given by Eq. 4, where *pSize* is population size.

$$p_{S}(I) = \frac{fitness(I)}{\sum_{j=1}^{pSize} fitness(j)}$$
(4)

Exploitation: recombination. An ad-hoc single point crossover operator is used to recombine solutions, in order to preserve the precedence relations between activities. Two parents $A = (A_0^0, A_1^a, \dots, A_{r-1}^b, A_r^c, \dots, A_{N+1}^0)$ and $B = (B_0^0, B_1^d, \dots, B_{r-1}^e, B_r^f, \dots, B_{N+1}^0)$ are selected from the population, and an integer r is selected randomly from the interval [1, N]. Then, two offspring C and D are generated according to r: $C = (\overline{A_0^0}, \overline{A_1^{a'}}, \dots, \overline{A_{r-1}^{b'}}, A_r^c, \dots, A_{N+1}^0)$ where $\overline{A_0^0}, \overline{A_1^{a'}}, \dots, \overline{A_{r-1}^{b'}}$ are the elements $A_0^0, A_1^a, \dots, A_{r-1}^b$ in A, but using the modes in B, and arranged in the order they are in B, and $D = (\overline{B_0^0}, \overline{B_1^{d'}}, \dots, \overline{B_{r-1}^{e'}}, B_r^f, \dots, B_{N+1}^b)$ where $\overline{B_0^0}, \overline{B_1^{d'}}, \dots, \overline{B_{r-1}^{e'}}$ are the elements B_1^d, \dots, B_{r-1}^e in B, but using the modes in A, and arranged in the order they are in A. So, each offspring inherits activities from one parent, half of them with the order and modes they have in the other parent. The crossover operator can generate solutions that exceed the maximum time allowed, so the feasibility check/repair method is used to assure that all constraints are met.

Exploration: mutation. Let $A = (A_0^0, ..., A_p^*, ..., A_r^k, ..., A_s^*, ..., A_{N+1}^0)$ be the individual that is selected for mutation, where A_p^* denotes the activity A_p in any (fixed) mode. An integer r is selected at random from the interval [1, N]. Let activity A_p be the last predecessor of activity A_r , and let activity A_s be the first successor of activity A_r . An integer d is selected randomly from the interval [p + 1, s - 1], then:

$$d \leq r \rightarrow A' = (A_0^0, A_1^*, \dots A_p^*, A_r^{k'}, A_{p+1}^*, \dots A_{r-1}^*, A_{r+1}^* \dots A_{N+1}^0) d > r \rightarrow A' = (A_0^0, A_1^*, \dots A_{r-1}^*, A_{r+1}^*, \dots A_{s-1}^*, A_r^{k'}, A_s^* \dots A_{N+1}^0)$$

The mutation operator maintains the precedence relations between activities, but the new mode is randomly selected, so the feasibility check/repair mechanism is applied to guarantee that the deadline constraint is met.

Local search. The local search operator attempts to improve a given solution $A = (A_0^0, A_1^a \dots, A_k^k, \dots, A_N^b, A_{N+1}^0)$ by evaluating to change the activities to a mode that reduces the total cost. Starting on a randomly selected activity a_i , the operator cyclically analyzes all the *N* activities, attempting to change it to mode $m_{i(k-1)}$, assuming that the activity is assigned to execute in mode m_{ik} . The process is iteratively applied until all activities have been analyzed and no change has been applied, because making such changes will imply to violate the deadline constraint. Thus, a new schedule $A' = (A_0^0, A_1^{a'} \dots, A_k^{b'}, \dots, A_N^{b'}, A_{N+1}^0)$ is generated. This operator maintains the precedence relations between activities and it also guarantees that the deadline constraint is not violated.

Parallel model. The proposed parallel EA uses a pool of t threads. Each thread executes all the operators, including the time-consuming LS operator and the feasibility check/repair mechanism (see a diagram in Figure 1). Each thread creates two new solutions, so a synchronizing procedure is required in order to build the new population.

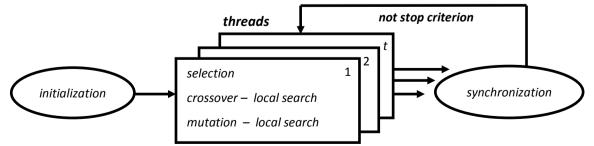

Figure 1: Master-slave model implemented in the proposed parallel EA.

6. Experimental analysis

This section introduces the set of DPPM instances and the platform used in the experimental evaluation. After that, the parameter setting experiments are commented. The last subsection presents and discusses the numerical results of the proposed parallel EA.

6.1. DPPM instances

Thirty-six complex instances in the benchmark from Akkan et al. (2005) are used to evaluate the proposed EA. The complexity is evaluated regarding two metrics: Coefficient of Network Complexity (CNC), the ratio between number of activities and number of modes, and Complexity Index (CI), that evaluates how close an instance to a series-parallel one is.

In the selected instances, the number of modes and the durations of each activity are selected using a discrete uniform distribution in [1, 10] and [3,123], respectively. The minimum cost $c_{i,1}$ is uniformly selected in [5,15] for all activity a_i , and $c_{i,k+1}$ is defined recursively by $c_{i,k+1} = c_{i,k} + \propto (t_{i,k} - t_{i,k+1})$, where \propto is also taken from a uniform distribution. The deadline values are defined by $T = T_{min} + \theta(T_{max} - T_{min})$ being T_{min} and T_{max} the shortest and longest project durations respectively, and $\theta \in \{0.15, 0.30, 0.45\}$.

6.2. Development and execution platform

The EAs was implemented in C++, using the GAlib library. The experimental analysis was performed on a HP server with an Opteron 6172 Magny Cours (24 cores) processor at 2.26 GHz, with 24 GB RAM, and CentOS Linux 5.2.

6.3. Parameter setting experiments

A study was performed to determine the best values of three EA parameters: *pSize*, and the crossover p_c and mutation p_m probabilities. The candidate values were: $pSize \in \{50, 75, 100\}, p_c \in \{0.85, 0.90, 0.95\}, and <math>p_m \in \{0.01, 0.05, 0.1\}$. Thirty executions of the proposed parallel EA were performed for two average-size DPPM instances, with CI=14, CNC=6, N=102, and $\theta = 0.15$. The best results were obtained when using the configuration $pSize=50, p_c=0.95, p_m=0.01$, showing the importance of the crossover operator to compute accurate solutions. No significant improvements were detected when increasing *pSize*, suggesting that using a larger population is not useful to improve the results quality.

6.4. Validation experiments

In the experimental evaluation, fifty executions of the proposed parallel EA were performed to solve each of the 36 DPPM instances studied, using from one to 24 threads. The parallel EA is compared against LBs for the problem computed using CPLEX and against the BAB method by Hafizoglu and Azizoglu (2010), which is, up to our knowledge, the best method to solve the DPPM, even outperforming the original method by Akkan et al (2005).

We defined two GAP metrics in order to compare the quality of the solutions computed by the proposed parallel EA against BAB and LBs. The GAP metrics are defined in Eq. 5, where $best_{PEA}$, $best_{BAB}$, and $best_{LB}$ are the cost of the best solution computed by the proposed parallel EA, BAB and the LB, respectively.

$$GAP_{BAB} = \frac{best_{PEA} - best_{BAB}}{best_{BAB}} \qquad GAP_{LB} = \frac{best_{PEA} - best_{LB}}{best_{LB}}$$
(5)

We also evaluated the wall-clock time required by the proposed parallel EA, and report a comparison with the sequential version using only one thread of execution.

Table 1 presents the experimental results obtained by the proposed parallel EA using 24 threads, and a comparison with BAB and LB regarding both the quality of solutions and the execution time. The best, average, and standard deviation results computed in 50 independent executions of the parallel EA are reported. In those cases where the proposed parallel EA found the optimal solution or it outperformed the BAB method—regarding either the cost of the best solution or the execution time—the results are marked in bold.

Table1: Experimental results and comparison versus BAB and LB.

The results in Table 1 show that the proposed parallel EA is an accurate method to solve the DPPM. Regarding the solution quality, the parallel EA outperformed BAB in **12** instances, 8 of them for CI = 13. The parallel EA also computed identical results than BAB but requiring significant less execution time in other **21** instances, especially when tight deadlines are imposed. The percentage of improvement in the project cost are slight, mainly due to the excellent results computed by BAB, one of the best existing exact method to solve the problem. However, by taking advantage of the local search operator, a maximum cost improvement of **4.67%** over the BAB solution was obtained for an instance with CI = 13, CNC = 8, 128 activities, and θ = 0.30. The proposed parallel EA required less than one minute of execution time in all but nine of the problem instances tackled. The comparison with LB indicates that the EA was able to compute at least **28** optimal solutions for the problem, and in the remaining eight instances the *GAP*_{LB} metric was always below **1%**.

Table 2 presents a comparison between the parallel EA using 24 threads and the sequential version, when using a predefined time stopping criterion of 60 seconds of execution time. The best, average, and standard deviation results computed in 50 independent executions of both parallel and sequential EA are reported. The Kruskal-Wallis test was applied to analyze the results distributions in order to verify the statistical significance of the parallel EA improvements over the sequential version. When the improvements are statistically significant with a confidence level of 99.9% (i.e. the *p*-value is less than 0.001), the cost value is marked in bold. In addition, the number of generations performed in 60 seconds to achieve the average and best cost value is also reported. The last column ($\Delta_{24/1}$) reports the percent of improvement obtained when using the parallel EA over the sequential EA.

Table 2: Parallel EA versus sequential EA.

The results in Table 2 demonstrate that the parallel model allows computing better solutions than the sequential EA. When using the time stop limit of 60 seconds, the average fitness values computed by the parallel EA outperformed the ones computed by the sequential version in all the instances, and regarding the best values the parallel EA found best solutions in 16 out of 36 instances. The largest solution improvement found by the parallel EA was 1.55% for an instance with CI = 13, CNC = 8, 128 activities, and θ = 0.15.

A summary of the results quality is presented in Figure 2, reporting the comparative improvements over the BAB algorithm (larger improvements are better), and the GAPs with respect to the LB (smaller GAPs are better).

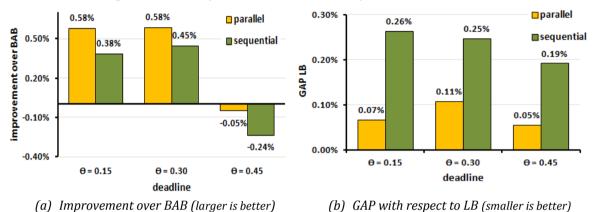

Figure 2: Summary of results, parallel EA and sequential EA versus BAB and LB.

The computational efficiency of the parallel version is significantly better than the sequential EA. The values of gen_{AVG} and gen_{BEST} reported in Table 2 and the values of gen_{AVG} summarized in Figure 3 indicate that the parallel EA allows performing more than four times the number of generations performed by the sequential version in 60 seconds. This feature permits the parallel EA to perform a better search and to compute better solutions.

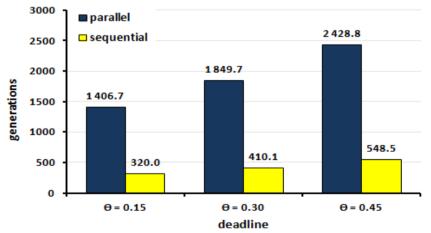

Figure 3: Summary of gen_{AVG} for the parallel EA and the sequential EA.

We also performed a scalability analysis of the parallel EA when varying the number of cores used. Figure 4 reports the average execution times required to perform a fixed number of generations (1000) for each value of the θ parameter. The time results demonstrate that tightest instances ($\theta = 0.15$) are the most difficult to solve, since both the feasibility check/repair and the local search demand larger computing times. Figure 4 also shows that the execution times reduce when using a larger number of cores. The average ratio between the execution times of the sequential EA (using one core) and the parallel EA using 24 cores is 3.9.

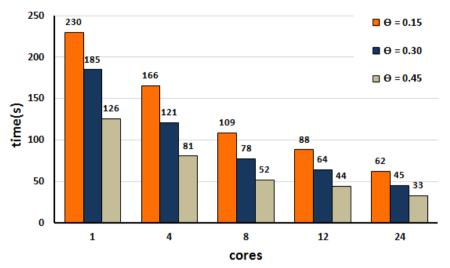

Figure 4: Scalability analysis of the parallel EA using different number of cores.

metric	sequential EA	parallel EA
outperform BAB	10 instances	12 instances
identical results to BAB	12 instances	21 instances
optimal solutions	21 instances	28 instances
maximum <i>GAP</i> _{LB}	1.2%	0.9%
average execution time (1000 generations)	180.3 seconds	46.6 seconds
		_

Overall, Table 3 summarizes the main results in the experimental analysis.

7. Conclusions and future work

This article presented an accurate and efficient parallel EA to solve the DPPM, an important problem in project management. The DPPM proposes to assign modes to activities in order to provide a good tradeoff between duration and cost, enabling the best project performance, while fulfilling deadline constraints on the total project duration.

The proposed parallel EA was designed to provide accurate and efficient solutions, by using operators that allow realistic problem instances to be solved in reduced execution times. Recombination, mutation, and local search operators have been specifically proposed to achieve this goal, and a feasibility check/repair method is incorporated in order to guarantee that the candidate solutions meet the problem constraints. In addition, a master-slave parallel model was implemented to improve the computational efficiency, extending the GAlib library by implementing a multithreading approach in C++.

The experimental evaluation of the proposed EA was performed on a set of 36 complex benchmark instances from Akkan (2005), regarding standard metrics for complexity. A comparative study against the BAB algorithm (Hafizoglu 2010), one of the best well-known deterministic techniques for the problem, was performed. The numerical results demonstrated that the proposed parallel EA is able to outperform BAB in terms of both quality of solutions and computational efficiency, especially when solving instances with tight deadlines. The proposed EA was able to find **12** new best-known solutions for the benchmark instances solved, obtaining cost improvement of up to **4.7**% over BAB. The EA also computed similar results than BAB but requiring significant less execution time in other **21** instances. The comparison with lower bounds indicates that the parallel EA was able to compute **28** optimal solutions out of the 36 problem instances tackled. A scalability analysis demonstrated that the parallel EA was able to execute four times more generations than the sequential version in a given time, and that the execution times reduce when using an increasing number of computational resources.

Table 3: Summary of parallel EA versus sequential EA results.

The previous results indicate that the proposed parallel EA is an accurate and efficient method to solve the DPPM, especially when dealing with tight deadlines. The main lines for future work are related with improving the evolutionary search and the computational efficiency of the proposed EA. Regarding the first line, new evolutionary operators can be designed in order to improve the results quality and allowing tackling larger problem instances. In addition, other parallel models of the proposed EAs can be applied in order to further improve the efficiency of the method.
