Model Selection and the Principle of Minimum Description Length

Mark H. Hansen and Bin Yu[1]

Abstract

This paper reviews the principle of Minimum Description Length (MDL) for problems of model selection. By viewing statistical modeling as a means of generating *descriptions* of observed data, the MDL framework discriminates between competing models based on the *complexity* of each description. This approach began with Kolmogorov's theory of algorithmic complexity, matured in the literature on information theory, and has recently received renewed interest within the statistics community. In the pages that follow, we review both the practical as well as the theoretical aspects of MDL as a tool for model selection, emphasizing the rich connections between information theory and statistics. At the boundary between these two disciplines, we find many interesting interpretations of popular frequentist and Bayesian procedures. As we will see, MDL provides an objective umbrella under which rather disparate approaches to statistical modeling can co-exist and be compared.

We illustrate the MDL principle by considering problems in regression, nonparametric curve estimation, cluster analysis, and time series analysis. Because model selection in linear regression is an extremely common problem that arises in many applications, we present detailed derivations of several MDL criteria in this context and discuss their properties through a number of examples. Our emphasis throughout this paper is on the practical application of MDL, and hence we make extensive use of real data sets. In writing this review, we tried to make the descriptive philosophy of MDL natural to a statistics audience by examining classical problems in model selection. In the engineering literature, however, MDL is being applied to ever more exotic modeling situations. As a principle for statistical modeling in general, one strength of MDL is that it can be intuitively extended to provide useful tools for new problems.

KEY WORDS: AIC; Bayesian Methods; BIC; Cluster Analysis; Code Length; Coding Redundancy; Information Theory; Minimum Description Length; Model Selection; Pointwise and Minimax Lower Bounds; Regression; Time Series.

1 Overview

The Principle of Parsimony or Occam's Razor implicitly motivates the process of data analysis and statistical modeling, and is the soul of model selection. Formally, the need for model selection arises when investigators have to decide among model classes based on data. These classes might be indistinguishable from the standpoint of existing subject-knowledge or scientific theory, and the selection of a particular model class implies the confirmation or revision of a given theory. To implement the Parsimony Principle, one has to quantify "parsimony" of a model relative to the available data. Applying this measure to a number of candidates, we search for a *concise* model that provides a *good fit* to the data. Rissanen (1978) distills such thinking in his Principle of Minimum Description Length (MDL):

Choose the model that gives the shortest description of data.

In this framework, a concise model is one that is easy to describe; while a good fit implies that the model captures or describes the important features evident in the data.

MDL has its intellectual roots in the algorithmic or descriptive complexity theory of Kolmogorov, Chaitin and Solomonoff (Li and Vitányi, 1996). Later in life, Kolmogorov, the founder of axiomatic probability theory, examined the relationship between mathematical formulations of randomness and their application to real-world phenomena. He ultimately turned to algorithmic complexity as an alternative means of expressing random events. A new characterization of probability emerged based on the length of the *shortest* binary computer program that *describes* an object (or event).[2] We refer to this quantity as the *descriptive complexity* of the object. Up to a constant, it can be defined independent of any specific computing device, making it a *universal* quantity (Kolmogorov, 1965, 1968; and Cover and Thomas, 1991). Because this descriptive complexity is universal, it provides a useful way to think about probability and other problems that build on fundamental notions of probability. In theory, it can also be used to define inductive inference in general (or statistical inference in particular) as the search for the shortest program for data.

Unfortunately, the descriptive complexity of Kolmogorov is not computable (cf. Cover and Thomas, 1991) and therefore impossible to use as a basis for inference given real data. Rissanen modifies this concept when proposing MDL, sidestepping computability issues. First, he restricts attention to only those descriptions that correspond to probability models or distributions (in the traditional sense); and then opts to emphasize the description length *interpretation* of these distributions rather than the actual finite-precision computations involved. In so doing, Rissanen derives a broad but usable principle for statistical modeling. By considering only probability distributions as a basis for generating descriptions, Rissanen endows MDL with a rich information-theoretic interpretation: description length can be thought of as the number of digits in a binary string used to *code* the data for transmission. Formally, then, he equates the task of "describing" data with coding. Not surprisingly, the development of MDL borrows heavily from Shannon's work on coding theory (Shannon, 1948). Because of the close ties, we will frequently use the terms code length and description length interchangeably. As we will see, the connection between MDL and information theory will provide us with new insights into familiar statistical procedures.

In Rissanen's formulation of MDL, any probability distribution is considered from a descriptive point of view, that is, it is not necessarily the underlying data-generating mechanism (although it does not exclude such a possibility). Thus MDL extends the more traditional random sampling approach to modeling. Many probability distributions can be compared in terms of their descriptive power and if the data in fact follow one of these models, then Shannon's celebrated source coding theorem (cf. Cover and Thomas, 1991) states that this "true" distribution gives the minimum description length of the data (on average and asymptotically).

[2] A program can "describe" an object by "printing" or in some way exhibiting the object. Typically, an object is a binary string, and exhibiting the string is nothing more than printing the individual 0's and 1's in order and stopping in finite time.

An important precursor to Rissanen's MDL is Wallace and Boulton (1968), which applies the idea of Minimum Message Length (MML) to clustering problems. While based on code length, MML exclusively employs a two-part coding formulation that is most natural in parametric families (see Section 4.2; Wallace and Freeman, 1987; and Baxter and Oliver, 1995). The original MML proposal stopped short of a framework for addressing other modeling problems, and recent advances seem to focus mainly on parameter estimation. In contrast, Rissanen formulated MDL as a broad principle governing statistical modeling in general. Two other approaches to model selection, which are influential and important in their own right, are those of Akaike (1974) and Schwarz (1978). In his derivation of AIC, A Information Criterion, Akaike (1974) gives for the first time formal recipes for general model selection problems from the point of view of prediction. It is fascinating to note the crucial role that the information-theoretic Kullback-Leibler divergence played in the derivation of AIC, since we will see in this article that Kullback-Leibler divergence is indispensable in the MDL framework. Schwarz (1978) takes a Bayesian approach to model selection deriving an approximation to a Bayesian posterior when the posterior exists. This approximate Bayesian model selection criterion has a form very similar to AIC and is termed the Bayesian Information Criterion, BIC.

MDL has connections to both frequentist and Bayesian approaches to statistics. If we view statistical estimation in a parametric family as selecting models (or distributions) indexed by the parameters, MDL gives rise to the Maximum Likelihood (ML) Principle of parameter estimation in classical statistics. It is therefore a generalization of the Maximum Likelihood principle to model selection problems where ML is known to fail. The performance of MDL criteria has been evaluated very favorably based on the random sampling or frequentist paradigm (e.g. Hannan and Rissanen, 1982; Hannan, McDougall and Poskitt, 1989; Wei, 1992; Speed and Yu, 1994; Lai and Lee, 1997; and Barron, Rissanen and Yu, 1998). Moreover, MDL has close ties with the Bayesian approach to statistics. For example, BIC has a natural interpretation in the MDL paradigm, and some forms of MDL coincide with Bayesian schemes (cf. Section 3). Because of the descriptive philosophy, the MDL paradigm serves as an objective platform from which we can compare Bayesian and non-Bayesian procedures alike.

The rest of the paper is organized as follows. Section 2 introduces basic coding concepts and explains the MDL principle. In particular, we start with Kraft's inequality, which establishes the equivalence between probability distributions and code lengths. We illustrate different coding ideas through a simple example of coding or compressing up-down indicators derived from daily statistics of the Dow-Jones Industrial Average. We emphasize that using a probability distribution for coding or description purposes does not require that it actually generates our data. We revisit MDL at the end of Section 2 to connect it with the Maximum Likelihood Principle and Bayesian statistics. We also define the notion of a "valid" description length, in the sense that valid coding schemes give rise to MDL selection rules that have provably good performance. (This issue is explored in depth in Section 5.) Section 3 formally introduces different forms of MDL such as two-stage (or multi-stage in general), mixture, predictive, and normalized maximized likelihood.

Section 4 contains applications of MDL model selection criteria in linear regression models, curve estimation, cluster analysis, and time series models. Our coverage on regression models is extensive. We compare well-known MDL criteria, to BIC and AIC through both simulations and real applications. These studies suggest an adaptive property of some forms of MDL, allowing them to behave like AIC or BIC, depending on which is more desirable in the given context (Hansen and Yu, 1999, further explores this property). Cluster analysis is also considered in Section 4, where we apply MML (Wallace and Boulton, 1968). We end this section by fitting an ARMA model to the Dow-Jones data sets, comparing predictive MDL ($PMDL$), BIC and AIC for order selection.

Section 5 reviews theoretical results on MDL. They are the basis or justification for different forms of MDL to be used in parametric model selection. In particular, we mention the remarkable pointwise lower bound of Rissanen (1986a) on expected (coding) redundancy and its minimax counterpart of Clarke and

Barron (1990). Both lower bounds are extensions of Shannon's source coding theorem to universal coding. Section 5 ends with an analysis of the consistency and prediction error properties of MDL criteria in a simple example.

2 Basic Coding Concepts and the MDL Principle

2.1 Probability and idealized code length

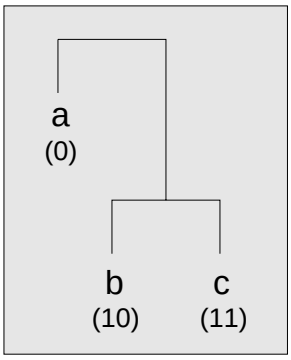
2.1.1 The discrete case

A *code* $\mathcal{C}$ on a set $\mathcal{A}$ is simply a mapping from $\mathcal{A}$ to a set of *codewords*. In this section, we will consider binary codes so that each codeword is a string of 0's and 1's. Let $\mathcal{A}$ be a finite set and let Q denote a probability distribution on $\mathcal{A}$. The fundamental premise of the MDL paradigm is that $-\log_2 Q$, the negative logarithm of Q, can be viewed as the code length of a binary code for elements or symbols in $\mathcal{A}$.

Example 1 (Huffman's Algorithm) Let $\mathcal{A} = \{a, b, c\}$ and let Q denote a probability distribution on $\mathcal{A}$ with $Q(a) = 1/2$ and $Q(b) = Q(c) = 1/4$. Following Huffman's algorithm (Cover and Thomas 1991, p. 92) we can construct a code for $\mathcal{A}$ by growing a binary tree from the end-nodes $\{a, b, c\}$. This procedure is similar to the greedy algorithm used in agglomerative, hierarchical clustering (Jobson, 1992). First, we choose the two elements with the smallest probabilities, b and c, and connect them with leaves 0 and 1, assigned arbitrarily, to form the intermediate node bc having node probability $1/4 + 1/4 = 1/2$. We then iterate the process with the new set of nodes $\{a, bc\}$. Since there are only two nodes left, we connect a and bc with leaves 0 and 1, again assigned arbitrarily, and reach the tree's root. The tree obtained through this construction as well as the resulting code are given explicitly in Figure 1. Let L be the code length function associated with this code so that $L(a) = L(0) = 1$, $L(b) = L(10) = 2$, and $L(c) = L(11) = 2$. It is easy to see that in this case, our code length is given exactly by $L(x) = -\log_2 Q(x)$ for all $x \in \mathcal{A}$. When we encounter ties in this process, Huffman's algorithm can produce different codes depending on how we choose which nodes to merge. For example, suppose that we start with a uniform distribution on $\mathcal{A}$, $Q(a) = Q(b) = Q(c) = 1/3$. At the first step in Huffman's algorithm, if we join a and b, the resulting code is $a \to 00$, $b \to 01$ and $c \to 1$. On the other hand, if we begin by joining b and c we arrive at the same code as in Figure 1. Fortunately, no matter how we handle ties, the expected length (under Q) of the resulting code is always the same; that is, the expected value of $L(x)$ computed under the distribution $Q(x)$ will be the same for all Huffman codes computed for $Q(x)$. □

Clearly, the Huffman code constructed in our example is not unique because we can permute the labels at each level in the tree. In addition, depending on how we settle ties between the merged probabilities at each step in the algorithm, we can obtain different codes with possibly different lengths. This point was illustrated in the example, where we also indicated that despite these differences, the expected length of the Huffman code (under the distribution Q) is always the same. An interesting feature of the code in Example 1 is that any string of 0's and 1's can be uniquely decoded without introducing separating symbols between the codewords. The string 0001110, for example, must have come from the sequence *aaacb*. Given an arbitrary code, if no codeword is the prefix of any other, then unique decodability is guaranteed. Any code satisfying this codeword condition is referred to as a *prefix code*. By taking their codewords as endnodes of a binary tree, all Huffman codes are in this class.

In general, there is a correspondence between the length of a prefix code and the quantity $-\log_2 Q$ for a probability distribution Q on $\mathcal{A}$. An integer-valued function L corresponds to the code length of a binary



$$\begin{aligned} \mathcal{C} : \mathcal{A} &\rightarrow \{0,1\}^* = \text{ strings of 0's and 1's} \\ a &\rightarrow 0 \\ b &\rightarrow 10 \\ c &\rightarrow 11 \end{aligned}$$

Figure 1: Constructing a Huffman code in Example 1: In the lefthand panel we present the binary tree on which the code is based; and on the right we exhibit the final mapping.

prefix code if and only if it satisfies Kraft's inequality

$$\sum_{x \in \mathcal{A}} 2^{-L(x)} \leq 1, \tag{1}$$

see Cover and Thomas (1991) for a proof. Therefore, given a prefix code $\mathcal{C}$ on $\mathcal{A}$ with length function L, we can define a distribution on $\mathcal{A}$ as follows,

$$Q(x) \;=\; \frac{2^{-L(x)}}{\sum_{z \in \mathcal{A}} 2^{-L(z)}} \quad \text{for any } x \in \mathcal{A}.$$

Conversely, for any distribution Q on $\mathcal{A}$ and any $x \in \mathcal{A}$, we can find a prefix code with length function $L(x) = \lceil -\log_2 Q(x) \rceil$, the smallest integer greater than or equal to $-\log_2 Q(x)$. Despite our good fortune in Example 1, Huffman's algorithm does not necessarily construct a code with this property for every distribution Q.[3]

Now, suppose that elements or symbols of $\mathcal{A}$ are generated according a known distribution P, or in statistical terms, we observe data drawn from P. Given a code $\mathcal{C}$ on $\mathcal{A}$ with length function L, the *expected code length* of $\mathcal{C}$ with respect to P is defined to be

$$L_{\mathcal{C}} = \sum_{x \in \mathcal{A}} P(x) L(x)\,. \tag{2}$$

As we have seen, if $\mathcal{C}$ is a prefix code, L is essentially equivalent to $-\log_2 Q$ for some distribution Q on $\mathcal{A}$. Shannon's Source Coding Theorem states that the expected code length (2) is minimized when $Q = P$, the true distribution of our data.

Theorem 1 (Shannon's Source Coding Theorem) *Suppose elements of $\mathcal{A}$ are generated according to a probability distribution P. For any prefix code $\mathcal{C}$ on $\mathcal{A}$ with length function L, the expected code length $L_{\mathcal{C}}$ is bounded below by $H(P)$, the entropy of P. That is,*

$$L_{\mathcal{C}} \;\geq\; H(P) \;\equiv\; -\sum_{a \in \mathcal{A}} P(a) \log_2 P(a), \tag{3}$$

where equality holds if and only if $L = -\log_2 P$.

[3] We can only guarantee that the length function L derived from Huffman's algorithm is within 2 of $\lceil -\log_2 Q \rceil$. While slightly more complicated, the Shannon-Fano-Elias coder produces a length function that satisfies $L = \lceil -\log_2 Q \rceil$ exactly (Cover and Thomas, 1991).

The proof of the "if" part of this theorem follows from Jensen's inequality and the "only if" part is trivial. Broadly, codes based on P remove *redundancy* from the data without any loss of information by assigning short codewords to common symbols and long codewords to rare symbols.[4] This is the same rationale behind Morse Code in telegraphy.

By applying Huffman's algorithm to the distribution P, we obtain a code that is nearly optimal in expected code length. Cover and Thomas (1991) prove that the Huffman code for P has an expected length no greater than $H(P) + 1$. We must emphasize, however, that any distribution Q defined on $\mathcal{A}$, not necessarily the data-generating or true distribution P, can be used to encode data from $\mathcal{A}$. In most statistical applications, the true distribution P is rarely known, and to a large extent, this paper is concerned with codes built from various approximations to P.

Ultimately, the crucial aspect of the MDL framework is not found in the specifics of a given coding algorithm, but rather in the code length interpretation of probability distributions. For simplicity, we will refer to $L_Q = -\log_2 Q$ as the *code length* of (the code corresponding to) a distribution Q, whether or not it is an integer. The unit is a *bit*, which stands for *bi*nary digi*t* and is attributed to John W. Tukey. (Later in the paper, we will also use the unit *nat* when a natural logarithm is taken.)

Example 2 (Code length for finitely many integers) Consider the finite collection of integers $\mathcal{A} = \{1, 2, 3, \ldots, N\}$ and let Q denote the uniform distribution on $\mathcal{A}$, so that $Q(k) = 1/N$ for all $k \in \mathcal{A}$. Let $\rfloor \log_2 N$ be the integer part of $\log_2 N$. By applying Huffman's algorithm in this setting, we obtain a uniform code with length function that is not greater than $\rfloor \log_2 N$ for all k, but is equal to $\rfloor \log_2 N$ for at least two values of k. While we know from Shannon's Source Coding Theorem that an expected code length of such a code is optimal only for a true uniform distribution, this code is a reasonable choice when very little is known about how the data were generated. This is simply a restatement of Laplace's Principle of Indifference which is often quoted to justify the assignment of uniform priors for a Bayesian analysis in discrete problems. □

Example 3 (Code length for natural numbers) Elias (1975) and Rissanen (1983) construct a code for the natural numbers $\mathcal{A} = \{1, 2, 3, \ldots\}$ starting with the property that the code length function decreases with $a \in \mathcal{A}$. The rate of decay is then taken to be as small as possible, subject to the constraint that the length function must still satisfy Kraft's inequality. Rissanen argues that the resulting prefix code is "universal" in the sense that it achieves essentially the shortest coding of large, natural numbers. Its length function is given by

$$\log_2^* n := \sum_{j>1} \max(\log_2^{(j)} n, 0) + \log_2 c_0, \tag{4}$$

where $\log_2^{(j)}(\cdot)$ is the jth composition of $\log_2$, e.g., $\log_2^{(2)} n = \log_2 \log_2 n$; and

$$c_0 := \sum_{n>1} 2^{-\log_2^* n} = 2.865\ldots$$

□

2.1.2 The continuous case

Suppose that our data is no longer restricted to a finite set, but instead range over an arbitrary subset of the real line. Let f denote the data-generating or true density. Given another density q defined on $\mathcal{A}$, we

[4] We provide a formal definition of redundancy in Section 5.

can construct a code for our data by first discretizing $\mathcal{A}$ and then applying, say, Huffman's algorithm. In most statistical applications, we are not interested in $\mathcal{A}$, but rather its Cartesian product $\mathcal{A}^n$ corresponding to an n-dimensional continuous data sequence $x^n = (x_1, \ldots, x_n)$. Then, if we discretize $\mathcal{A}$ into equal cells of size δ, the quantity $-\log_2(q(x^n) \times \delta^n) = -\log_2 q(x^n) - n\log_2 \delta$ can be viewed as the code length of a prefix code for the data sequence x^n. We say that δ is the precision of the discretization, and for fixed δ we refer to $-\log_2 q(x^n)$ as an *idealized code length*. In Section 3.1, we will return to discretization issues arising in modeling problems.

From a straightforward generalization of Shannon's Source Coding Theorem to continuous random variables, it follows that the best code for a data string x^n is based on its true or generating density $f(x^n)$. In this case, the lower bound on the expected code length is the differential entropy

$$H(f) = -\int \log_2 f(x^n) f(x^n) dx^n. \tag{5}$$

2.2 A simple example

In this section, we consider coding a pair of long, binary strings. We not only illustrate several different coding schemes, but we also explore the role of postulated probability models Q in building good codes. This is a valuable exercise, whether or not it is appropriate to believe that these strings are actually generated by a specific probabilistic mechanism. Although our emphasis will be on coding for compression purposes, we have framed the following example so as to highlight the natural connection between code length considerations and statistical model selection. Each of the coding schemes introduced here will be discussed at length in the next section when we take up modeling issues in greater detail.

Example 4 (Code length for finite, binary strings) For the 6430-day trading period between July, 1962 and June, 1988, we consider two time series derived from the Dow-Jones Industrial Average (DJIA). Let P_t denote the logarithm of the index at day t and define the daily *return*, R_t, and the intra-day *volatility*, V_t, to be

$$R_t = P_t - P_{t-1} \qquad \text{and} \qquad V_t = 0.9V_{t-1} + 0.1R_t^2\,, \tag{6}$$

where V_0 is the unconditional variance of the series P_t. The data for this example were taken from the URL `http://ssdc.ucsd.edu/ssdc/NYSE.Date.Day.Return.Volume.Vola.text`, where one can also find references for the definitions (6).

Consider two "up and down" indicators derived from the daily return and intra-day volatility series. The first takes the value 1 if the return R_t on a given day was higher than that for the previous day R_{t-1} (an "up"), and 0 otherwise (a "down"). In terms of the original (logged) DJIA series P_t, we assign the value 1 if $P_t - 2P_{t-1} + P_{t-2} \geq 0$, so that our first indicator is derived from a moving average process. The second variable is defined similarly, but instead tracks the volatility series, making it a function of another moving average process. This gives us two binary strings of length $n = 6430 - 1 = 6429$. There are 3181 or 49.49% 1s or ups in the return difference indicator string, compared with 2023 or 31.47% 1's in the volatility difference string. In Figure 2, we present the last 1,000 observations from each series. To coordinate with our construction of binary strings, we have plotted daily differences so that ups correspond to positive values and downs to negative values. In the panels below these plots, we have greyscale maps representing the average number of up's calculated in ten-day intervals (black representing ten consecutive trading days for which the given series increased; white indicating a period of ten down's). The activity clearly evident at the right in these plots corresponds to the stock market crash of October 19, 1987. As one might expect,

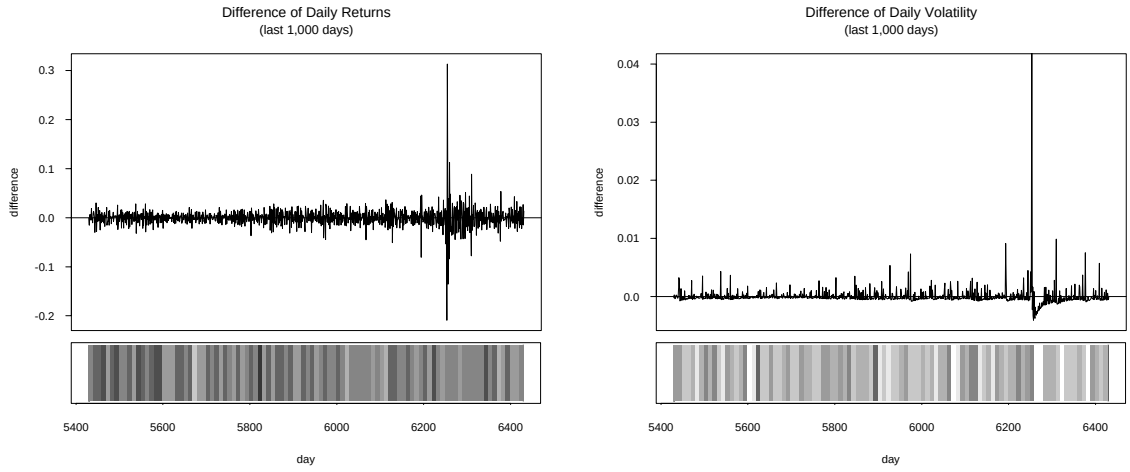


Figure 2: Differences of the volatility and return series. The last 1000 The horizontal line in each plot corresponds to $y = 0$. The greyscale maps represent the average number of up's calculated in ten-day intervals (black representing ten consecutive trading days for which the given series increased; while indicating a period of ten down's).

the intra-day volatility jumped dramatically, while the overall return was down sharply from the previous day.

Using these strings, we will describe three coding algorithms, each assuming that the length of the string, $n = 6429$, is known to both sender and receiver. Imagine, for example, that a financial firm in San Francisco needs to transmit this up-and-down information to its branch in San Diego. Clearly, each string can be transmitted directly without any further coding, requiring $n = 6429$ bits. By entertaining different probability distributions, however, we might be able to decrease the code length needed to communicate these sequences.

Two-stage Coding. Suppose the sender uses a Bernoulli(p) model to send the series. Then p has to be estimated from the series and sent first. Let k be the number of ups in the series, so that there are only n different $p = k/n$'s one could send. Employing the uniform coding scheme of Example 2, this takes $\log_2 n = 6429$ or 13 bits. Once p is known to both sender and receiver it can be used in the next stage of coding. For example, suppose we view a string $x^n = (x_1, \ldots, x_n) \in \{0,1\}^n$ as n iid observations from the Bernoulli distribution with $p = k/n$. From the form of this distribution, it is easy to see that we can encode every symbol in the string at a cost of $-\log_2(k/n)$ bits for a 1 and $-\log_2(1 - k/n)$ bits for a 0. Therefore, transmitting each sequence requires an additional $-k\log_2(k/n) - (n-k)\log_2(1-k/n)$ bits after p is known, giving us a total code length of

$$\log_2 n + [-k\log_2(k/n) - (n-k)\log_2(1-k/n)]. \tag{7}$$

Under this scheme, we pay 6441 (> 6429) bits to encode the ups and downs of the return series, but only 5789 (< 6429) bits for the volatility series. Therefore, relative to sending this information directly, we incur an extra cost of 0.2% on the return string, but save 10% on the volatility string.

From a modeling point of view, we could say that an iid Bernoulli model is postulated for compression or coding of a given string and that the Bernoulli probability p is estimated by k/n. The first term

in (7) is the code length for sending k or the estimated p, while the second term is the code length for transmitting the actual string using the Bernoulli model or encoder. The success of the probability model is determined by whether there is a reduction in code length relative to the n bits required without a model. From the second term in (7), we expect some improvement provided k/n is not too close to $1/2$, and this saving should increase with n. When $k = n/2$, however,

$$-k \log_2(k/n) - (n-k) \log_2(1-k/n) = n\,,$$

and the Bernoulli model does not help. Considering our daily up-and-down information, we were able to decrease the code length for transmitting the volatility string by about 10% because the proportion of 1's in this sequence is only 0.31. For the return string, on the other hand, the proportion of ups is close to $1/2$, so that the second term in (7) is 6428, just one bit shy of $n = 6429$. After adding the additional 13 bit cost to transmit p, the Bernoulli encoder is outperformed by the simple listing of 0's and 1's.

Mixture Coding (with a uniform prior). If we assume that each binary string consists of iid observations, then by independence we obtain a joint distribution on x^n which can be used to construct a coder for our daily up-and-down information. Suppose, for example, that we postulate an iid Bernoulli model, but rather than estimate p, we assign it a uniform prior density on $[0, 1]$. We can then apply the resulting mixture distribution to encode arbitrary binary strings. If, for example, a sequence $x^n = (x_1, \ldots, x_n)$ consists of k 1's and $(n-k)$ 0's, then

$$m(x^n) = \int_0^1 p^k (1-p)^{n-k} dp = \frac{,\,(k+1),\,(n-k+1)}{,\,(n+2)} = \frac{k!(n-k)!}{(n+1)!},$$

where m is used to denote a "mixture." Therefore, the code length of this (uniform) mixture code is

$$-\log_2 m(x^n) = -\log_2 k!(n-k)! + \log_2(n+1)!. \tag{8}$$

In terms of our original binary series, by using this mixture code we incur a cost of 6434 bits to transmit the return string and 5782 bits for the volatility binary string. While consistent with our results for two-stage coding, we have saved 7 bits on both sequences. So far, however, we have yet to design a coding scheme that costs less than $n = 6429$ bits for the return indicators.

Although many mixture codes can be created by making different choices for the prior density assigned to p, the distribution $m(\cdot)$ is only guaranteed to have a closed form expression for a family of so-called conjugate priors. In general, numerical or Monte Carlo methods might be necessary to evaluate the code length of a mixture code.

Predictive Coding. Imagine that the up-and-down information for the return series was to be sent to San Diego on a daily basis, and assume that the sender and receiver have agreed to use a fixed code on $\{0, 1\}$. For simplicity, suppose they have decided on a Bernoulli encoder with $p = 1/2$. Each day, a new indicator is generated and sent to San Diego at a cost of $-\log_2(1/2) = 1$ bit. For the following 6429 days, this would total 6429 bits. (This is equivalent to simply listing the data without introducing a model.) Such a coding scheme could not be very economical if, on average, the number of "up days" was much smaller than the number of "down days" or vice versa. If instead we postulate an iid Bernoulli model with an unknown probability p, then all the previous information, known to both sender and receiver, can be used to possibly improve the code length needed to transmit the sequence. Suppose that over the past $t-1$ days, k_{t-1} ups or 1's have been accumulated. At day t,

a new Bernoulli coder can be used with the Laplace estimator $\hat{p}_{t-1} = (k_{t-1}+1)/(t+1)$, avoiding difficulties when $k_{t-1} = 0$ or $t-1$. At the outset, sender and receiver agree to take $p_0 = 1/2$. If on day t we see an increase in the return of the DJIA, then the Bernoulli coder with $p = \hat{p}_{t-1}$ is used at a cost of $L_t(1) = -\log_2 \hat{p}_{t-1}$ bits. Otherwise, we transmit a 0, requiring $L_t(0) = -\log_2(1-\hat{p}_{t-1})$ bits[5]. For a string $x^n = (x_1, ..., x_n)$ with k 1's and $(n-k)$ 0's, the total code length over 6429 days is

$$\sum_{t=1}^{n} L_t(x_t).$$

Equivalently, a joint probability distribution on $\{0,1\}^n$ has been *constructed predictively*:

$$q(x^n) = \prod_{t=1}^{n} \hat{p}_{t-1}^{x_t}(1-\hat{p}_{t-1})^{1-x_t}, \tag{9}$$

where

$$-\log_2 q(x^n) = \sum_{t=1}^{n} L_t(x_t).$$

Rewriting (9), we find

$$\begin{aligned}
-\log_2 q(x^n) &= -\sum_{t=1}^{n}[x_t \log_2 \hat{p}_{t-1} + (1-x_t)\log_2(1-\hat{p}_{t-1})] \\
&= -\sum_{t:x_t=1} \log_2 \hat{p}_{t-1} - \sum_{t:x_t=0} \log_2(1-\hat{p}_{t-1}) \\
&= -\sum_{t:x_t=1} \log_2(k_{t-1}+1) - \sum_{t:x_t=0} \log_2(t-k_{t-1}) + \sum_{t=1}^{n} \log_2(t+1) \\
&= -\log_2 k! - \log_2(n-k)! + \log_2(n+1)!
\end{aligned}$$

which is exactly the same expression as (8), the code length derived for the uniform mixture code (an unexpected equivalence that we will return to shortly). Although the bits are counted differently, the code lengths are the same. Therefore, from the previous example, the predictive code lengths are 6434 bits and 5782 bits for the return and volatility strings, respectively. In some sense, the predictive coder is designed to learn about p from the past up-and-down information, and hence improves the encoding of the next day's indicator. This form of coding enjoys intimate connections with machine learning (with its focus on accumulative prediction error; see Haussler, Kearns and Schapire, 1994) and the prequential approach of P. Dawid (1984, 1991). Clearly, predictive coding requires an ordering of the data which is very natural in on-line transmission and time series models, but conceptually less appealing in other contexts like multivariate regression. As in this case, however, when a proper Bayes estimator is used in the predictive coder, the ordering can sometimes disappear

[5] This accounting makes use of so-called "fractional bits." In practical terms, it is not possible to send less than a single bit of information per day. If we delay transmission by several days, however, we can send a larger piece of the data at a much lower cost. When the delay is n days, this "predictive" method is equivalent to the batch scheme used in mixture coding (sending the entire data string at once). We have chosen to sidestep this important practical complication and instead present predictive coding as if it could be implemented on a daily basis. The broad concept is important here as it is similar to other frameworks for statistical estimation, including P. Dawid's prequential analysis.

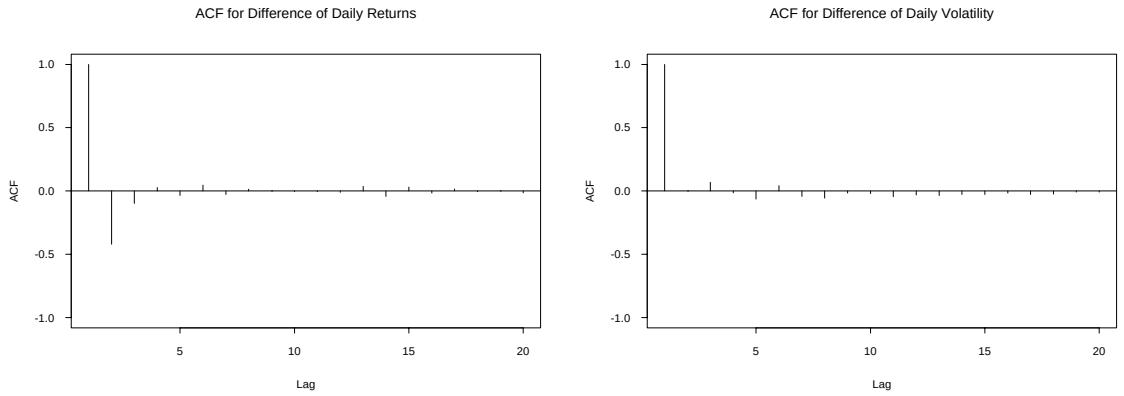

Figure 3: Autocorrelation functions for the differences of the volatility and return series. With 6429 points, the usual confidence intervals barely appear as distinct from the solid line $y = 0$.

in the final expression for code length. A proof of this somewhat surprising equivalence between predictive and mixture code lengths can be found, for example, in Yu and Speed (1992) for a general multinomial model.

In the time-series context, predictive coding offers us the ability to easily adapt to non-stationarity in the data source, a tremendous advantage over the other schemes discussed so far. For example, suppose that we only use the number of ups encountered in the last 1000 days to estimate p in a Bernoulli model for the next day's indicator. When applied to the volatility difference indicator series, we save only 3 bits over the 5782 needed for the simple predictive coder, implying that this string is fairly stationary. To explore the possible dependence structure in the volatility difference indicator string, we postulated a first-order Markov model, estimating the transition probabilities from the indicators for the last 1000 days. Under this scheme, we incur a cost of 5774 bits. Such a small decrease is evidence that there is little dependence in this string, and that the biggest saving in terms of code length comes from learning the underlying probability p in an iid Bernoulli model. This is because the volatility difference series $V_t - V_{t-1}$ exhibits very little correlation structure, despite of the fact that volatility series itself is an exponentially-weighted moving average. In Figure 3 we plot the autorcorrelation function for each of the differenced volatility and return series. In terms of the derived up-and-down indicators, the volatility string has a first-order autocorrelation of -0.02, practically non-existent.

The indicator string derived from the return series, however, is a different story. As with the volatility string, estimating p based on the previous 1000 days' data does not result in a smaller code length, suggesting little non-stationarity. However, there is considerably more dependence in the return string. While the underlying series R_t has little autocorrelation structure, the differences $R_t - R_{t-1}$ exhibit a large dependence at a lag of 1 (see Figure 3). The first-order autocorrelation in the return difference indicator string is -0.42, indicating that our Markov model might be more effective here than for the volatility string. In fact, by postulating a first-order Markov model (estimating transition probabilities at time t from all the previous data), we reduce the code length to 6181, a 4% or 253 bit saving over the 6434 bits required for the simple predictive coder. By instead estimating the transition probabilities from the last 1000 days of data, we can produce a further decrease of only 10 bits, confirming our belief that the return difference indicator string is fairly stationary. Under

this coding strategy, we are finally able to transmit the return string using fewer that $n = 6429$ bits.

In general, predictive coding can save in terms of code length even when we are considering an iid model. When dependence or non-stationarity are present, we can experience even greater gains by directly modeling such effects, say through a Markov model. Of course, with some effort the two-stage and mixture coding schemes can also incorporate these features, and we should see similar code length reductions when the data support the added structure. □

2.3 The MDL principle

In the previous two sections we motivated the code length interpretation of probability distributions and illustrated the use of models for building good codes. While our focus was on compression, motivation for the MDL principle can be found throughout Example 4: probability models for each binary string were evaluated on the basis of their code length. In statistical applications, postulated models help us make inferences about data. The MDL principle in this context suggests choosing the model that provides the shortest description of our data. For the purpose of this paper, the act of describing data is formally equivalent to coding. Therefore, when applying MDL, our focus is on casting statistical modeling as a means of generating codes, the resulting code lengths providing a metric by which we can compare competing models. As we found in Example 4, we can compute a code length without actually exhibiting a code (i.e., generating the map between data values and code words), making the implementation details somewhat unimportant.

As a broad principle, MDL has rich connections with more traditional frameworks for statistical estimation. In classical parametric statistics, for example, we want to estimate the parameter θ of a given model (class)

$$\mathcal{M} = \{f(x^n|\theta) : \theta \in \Theta \subset \mathbb{R}^k\}$$

based on observations $x^n = (x_1, \ldots, x_n)$. The most popular estimation technique in this context is derived from the Maximum Likelihood Principle (ML) pioneered by R. A. Fisher (cf. Edwards, 1972). Estimates $\hat{\theta}_n$ are chosen so as to maximize $f_\theta(x^n)$ over $\theta \in \Theta$. As a principle, ML is backed by $\hat{\theta}_n$'s asymptotic efficiency in the repeated-sampling paradigm (under some regularity conditions) and its attainment of the Cramer-Rao information lower bound in many exponential family examples (in the finite sample case). From a coding perspective, assume that both sender and receiver know which member f_θ of the parametric family $\mathcal{M}$ generated a data string x^n (or equivalently, both sides know θ). Then Shannon's Source Coding Theorem states that the best description length of x^n (in an average sense) is simply $-\log f_\theta(x^n)$, because on average the code based on f_θ achieves the entropy lower bound (5). In modeling applications like those discussed in Example 4, however, we had to transmit θ because the receiver did not know its value in advance. Adding in this cost, we arrive at a code length

$$-\log f_\theta(x^n) + L(\theta)$$

for the data string x^n. Now, if each parameter value requires the same fixed number of bits to transmit, or rather $L(\theta)$ is constant, then the MDL principle seeks a model that minimizes $-\log f_\theta(x^n)$ among all densities in the family. (This is the case if we transmit each value of θ with a fixed precision.) Obviously minimizing $-\log_2 f_\theta(x^n)$ is the same as maximizing $f_\theta(x^n)$, so that MDL coincides with ML in parametric estimation problems. Therefore, in this setting MDL enjoys all of the desirable properties of ML mentioned above.

It is well known, however, that maximum likelihood breaks down when we are forced to choose among nested classes of parametric models. This occurs most noticeably in variable selection for linear regression. The simplest and most illustrative selection problem of this type can be cast as an exercise in hypothesis testing:

Example 5 Assume $x^n = (x_1, \ldots, x_n)$ are n iid observations $N(\theta, 1)$ for some $\theta \in \mathbb{R}^1$, and we want to test the hypothesis $H_0 : \theta = 0$ versus $H_1 : \theta \neq 0$. Equivalently, we want to choose between the models

$$\mathcal{M}_0 = \{N(0,1)\} \quad \text{and } \mathcal{M}_1 = \{N(\theta, 1) : \theta \neq 0\}$$

on the basis of x^n. In this case, if we maximize the likelihoods of both models and choose the one with the larger maximized likelihood then $\mathcal{M}_1$ is always chosen unless $\bar{x}_n = 0$, an event with probability 0 even when $\mathcal{M}_0$ is true. □

Notice that ML has no problem with the estimation of θ if we merge the two model classes $\mathcal{M}_0$ and $\mathcal{M}_1$. It is clear that the formulation of the model selection problem is responsible for the poor performance of ML. To be fair, the ML principle was developed only for a single parametric family, and hence it is not guaranteed to yield a sensible selection criterion.

The Bayesian approach to statistics has a natural solution to this selection problem. After assigning a prior probability distribution to each model class, the Bayesian appeals to the posterior probabilities of these classes to select a model (see, for example, Bernardo and Smith, 1994). Given the formulation of the above problem, the assignment of priors is a subjective matter, which in recent years has been made increasingly on the basis of computational efficiency. Some attempts have been made to reduce the level of subjectivity required from such an analysis, producing "automatic" or "quasi-automatic" Bayesian procedures (O'Hagan, 1995; and Berger and Pericchi, 1996). A simple solution involves the use of BIC, an approximation to the posterior distribution on model classes derived by Schwarz (1978). While based on the assumption that proper priors have been assigned to each class, this approximation effectively eliminates any explicit dependence on prior choice. The resulting selection rule takes on the form of a penalized log-likelihood, $-\log f_{\hat{\theta}_n}(x^n) + \frac{k}{2}\log n$, where $\hat{\theta}_n$ is the ML estimate of the k-dimensional parameter θ.

To repair ML in this context, recall that Fisher first derived the likelihood principle within a single parametric family, starting from a Bayesian framework and placing a uniform prior on the parameter space (Edwards, 1972). Let $L_{\mathcal{M}}$ denote the description length of a data string x^n based on a single family or model (class) $\mathcal{M}$. Because MDL coincides with ML when choosing among members of $\mathcal{M}$, we can think of $2^{-L_{\mathcal{M}}}$ as the "likelihood" of the class given x^n. Now, applying Fisher's line of reasoning to models, we assign a uniform prior on different families and maximize the newly defined "likelihood." This yields the principle of MDL for model selection.

In Example 4, however, we presented several different coding schemes that can be used to define the description length $L_{\mathcal{M}}$ of a given model class $\mathcal{M}$. While many more are possible, not all of them are usable for statistical model selection. As our emphasis is on a coding *interpretation*, we would like to know under what general conditions these schemes provide us with "valid" description lengths based on $\mathcal{M}$ (in the sense that they yield selection rules with provably good performance). At an intuitive level, we should select a code that adequately represents the knowledge contained in a given model class, a notion that we make precise in Section 5. When characterizing the statistical properties of MDL criteria, Rissanen's (1986a) pointwise lower bound on the redundancy for parametric families is a landmark. Roughly, the expected redundancy of a code corresponds to the price one must pay for not knowing which member of the model class generated the data x^n. Rissanen (1986a) demonstrates that for a regular parametric family of dimension k, this amounts to at least $\frac{k}{2}\log n$ extra bits. Any code length that achieves this lower bound qualifies (to first order in the parametric case) as a valid description length of the model class given a data string x^n, and the associated model selection criteria have good theoretical properties.

An alternative measure for studying description length comes from a minimax lower bound on redundancy derived by Clarke and Barron (1990). Both the pointwise and minimax lower bounds not only make

compelling the use of MDL in statistical model selection problems, but also extend Shannon's Source Coding Theorem to so-called *universal coding* where the source or true distribution is only known to belong to a parametric family. A more rigorous treatment of this theoretical material is presented in Section 5. It follows from these results that $-\log f_{\hat{\theta}_n}(x^n) + \frac{k}{2}\log n$ (modular a constant term) is a valid code length for our parametric family introduced at the beginning of this section. We recognize this expression as BIC. More careful asymptotics yields a tighter bound on redundancy that can only be met if Jeffreys' prior is integrable in the particular family under study (see Barron et al., 1998).

The appearance of BIC as a valid code length and the more refined result about Jeffreys' prior are just two of a number of connections between MDL and Bayesian statistics. Among the various forms of MDL presented in Example 4, mixture coding bears the closest direct resemblance to a Bayesian analysis. For example, both frameworks can depend heavily on the assignment of priors, and both are subject to the requirement that the corresponding marginal (or predictive) distribution of a data string is integrable. When this integrability condition is not met, the Bayesian is left with an indeterminant Bayes factor; and the connection with prefix coding is lost (as Kraft's inequality is violated).[6] Both schemes also benefit from "realistic" priors, although the classes entertained in applications tend to be quite different.[7] In terms of loss functions, since MDL minimizes the mixture code length, it coincides with a Maximum A Posteriori (MAP) estimate derived using 0-1 loss. MDL parts company with Bayesian model selection in the treatment of hyperparameters that accompany a prior specification. Rissanen (1989) proposes a (penalized) maximum likelihood approach that we will examine in detail in Section 4.1.1 for ordinary regression problems. Also, given Kraft's inequality, MDL technically allows for sub-distributions. In applications involving discrete data, it is often the case that the only available coding scheme does not sum to one, or equivalently is not *Kraft-tight*.

In addition to mixture MDL, we have applied both two-stage and predictive coding schemes to the indicator series from Example 4. In the next section, we will introduce one more code based on the so-called normalized maximized likelihood. While these forms do not have explicit Bayesian equivalents, they can be thought of as building a marginal density over a model class or parametric family that is independent of the parameters. Hence, when the code for the model class corresponds to a proper distribution, or is Kraft-tight, one can borrow Bayesian tools for the assessment of uncertainty among candidate models. (This type of analysis has not been explored in the MDL literature.) In general, MDL formally shares many aspects of both frequentist and Bayesian approaches to statistical estimation. As Rissanen has commented in several of his papers, MDL provides an objective and welcome platform from which to compare (possibly quite disparate) model selection criteria. We are confident that the rich connections between information theory and statistics will continue to produce new forms of MDL as the framework is applied to more and more challenging problems.

3 Different Forms of Description Length based on a Model

In this section, we formally introduce several coding schemes that provide *valid* description lengths of a data string based on classes of probability models, in that sense that they achieve the universal coding lower bound to the $\log n$ order (cf. Section 5). The description lengths discussed here will be used in our implementation of MDL for the model selection problems in Sections 4 and 5. Three of these schemes

[6] This situation is most commonly encountered under the assignment of so-called weak prior information that leaves the marginal distribution improper. For example, as improper priors are specified only up to a multiplicative constant, the associated Bayes factor (a ratio of predictive or marginal densities) inherits an unspecified constant.

[7] MDL has found wide application in various branches of engineering. For the most part, Rissanen's reasoning is followed "in spirit" to derive effective selection criteria for the problem at hand. New and novel applications of MDL include generating codes for trees for wavelet denoising (Saito, 1994; and Moulin, 1996).

were introduced in Example 4 for compression purposes. In that case, probability models helped us build codes that could be employed to communicate data strings with as few bits as possible. The only necessary motivation for enlisting candidate models was that they provided short descriptions of the data. In statistical applications, however, probability distributions are the basis for making inference about data, and hence play a more refined role in modeling. In this section we follow the frequentist philosophy that probability models (approximately) describe the mechanism by which the data are generated.

Throughout this section, we will focus mainly on a simple parametric model class $\mathcal{M}$ consisting of a family of distributions indexed by a parameter $\theta \in \mathbb{R}^k$. Keep in mind, however, that the strength of the MDL principle is that it can be successfully applied in far less restrictive settings. Let $x^n = (x_1, x_2, \ldots, x_n)$ denote a data string, and recall our model class

$$\mathcal{M} = \{ f(x^n|\theta) : \theta \in \Theta \subset \mathbb{R}^k \}.$$

For convenience, we will consider coding schemes for data transmission, so that when deriving code or description lengths for x^n based on $\mathcal{M}$, we can assume that $\mathcal{M}$ is known to both sender and receiver. If this were not the case, we would also have to encode information about $\mathcal{M}$, adding to our description length. Finally, we will calculate code lengths using the natural logarithm log, rather than $\log_2$ as we did in the previous section. The unit of length is now referred to as a *nat*.

In the next few pages, we revisit the three coding schemes introduced briefly in Example 4. We derive each in considerably more generality and apply them to the hypothesis testing problem of Example 4. Building on this framework, in Section 4 we provide a rather extensive treatment of MDL for model selection in ordinary linear regression. A rigorous justification of these procedures is postponed to Section 5. There, we demonstrate that in the simple case of a parametric family, these coding schemes give rise to code lengths that all achieve (to first order) both Rissanen's pointwise lower bound on redundancy as well as the minimax lower bound to be covered in Section 5 (Clarke and Barron, 1990). This implies that these schemes produce valid description lengths, each yielding a usable model selection criterion via the MDL principle.

3.1 Two-stage Description Length

To a statistical audience, the two-stage coding scheme is perhaps the most natural method for devising a prefix code for a data string x^n. We first choose a member of the class $\mathcal{M}$ and then use this distribution to encode x^n. Because we are dealing with a parametric family, this selection is made via an estimator $\hat{\theta}_n$ after which a prefix code is built from $f_{\hat{\theta}_n}$. Ultimately, the code length associated with this scheme takes the form of a penalized likelihood, the penalty being the cost to encode the estimated parameter values $\hat{\theta}_n$.

Stage 1: *The description length $L(\hat{\theta}_n)$ for the estimated member $\hat{\theta}_n$ of the model class.*
In the first stage of this coding scheme, we communicate an estimate $\hat{\theta}_n$ (obtained by, say, ML or some Bayes procedure). This can be done by first discretizing a compact parameter space with precision $\delta_m = 1/\sqrt{n}$ (m for the model) for each member of θ, and then transmitting $\hat{\theta}_n$ with a uniform encoder. Rissanen (1983, 1989) shows that this choice of precision is optimal in regular parametric families. The intuitive argument is that $1/\sqrt{n}$ represents the magnitude of the estimation error in $\hat{\theta}_n$ and hence there is no need to encode the estimator with greater precision. In general, our uniform encoder should reflect the convergence rate of the estimator we choose for this stage. Assuming the standard parametric rate $1/\sqrt{n}$, we will pay a total of $-k \log \frac{1}{\sqrt{n}} = \frac{k}{2} \log n$ nats to communicate an estimated parameter $\hat{\theta}_n$ of dimension k.

Although the uniform encoder is a convenient choice, we can take any continuous distribution w on the parameter space and build a code for $\hat{\theta}_n$ by again discretizing with the same precision $\delta_m = 1/\sqrt{n}$:

$$L(\hat{\theta}_n) = -\log w([\hat{\theta}_n]_{\delta_m}) + \frac{k}{2} \log n,$$

where $[\hat{\theta}_n]_{\delta_m}$ is $\hat{\theta}_n$ truncated to precision δ_m. In the MDL paradigm, the distribution w is introduced as an ingredient in the coding scheme and not as a Bayesian prior. However, if we have reason to believe that a particular prior w reflects the likely distribution of the parameter values, choosing w for description purposes is certainly consistent with Shannon's Source Coding Theorem. It is clear that both recipes lead to description lengths with the same first order term

$$L(\hat{\theta}_n) \approx \frac{k}{2} \log n,$$

where k is the Euclidean dimension of the parameter space.

Stage 2: *The description length of data based on the transmitted distribution.*
In the second stage of this scheme, we encode the actual data string $x^n = (x_1, \ldots, x_n)$ using the distribution indexed by $[\hat{\theta}_n]_{\delta_m}$. For continuous data, we follow the prescription in Section 2.1.2, discretizing the selected distribution with precision δ_d (d for the data). In this stage, we can take δ_d to be machine precision. The description length for coding x^n is then

$$-\log f(x_1, \ldots, x_n | [\hat{\theta}_n]_{\delta_m}) - n \log \delta_d.$$

When the likelihood surface is smooth as in regular parametric families, the difference

$$\log f(x_1, \ldots, x_n | [\hat{\theta}_n]_{\delta_m}) - \log f(x_1, \ldots, x_n | \hat{\theta}_n)$$

is of a smaller order of magnitude than the model description length $\frac{k}{2} \log n$. In addition, the quantity $n \log \delta_d$ is constant for all the models in $\mathcal{M}$. Hence we often take

$$-\log f(x_1, \ldots, x_n | \hat{\theta}_n),$$

the negative of the maximized log-likelihood for the MLE $\hat{\theta}_n$, as the simplified description length for a data string x^n based on $f(\cdot|\hat{\theta}_n)$.

Combining the code or description lengths from the two stages of this coding scheme, we find that for regular parametric families of dimension k, the (simplified) two-stage MDL criterion takes the form of BIC

$$-\log f(x_1, \ldots, x_n | \hat{\theta}_n) + \frac{k}{2} \log n. \tag{10}$$

Again, the first term represents the number of nats needed to encode the date sequence x^n given an estimate $\hat{\theta}_n$, while the second term represents the number of nats required to encode the k components of $\hat{\theta}_n$ to precision $1/\sqrt{n}$. It is worth noting that the simplified two-stage description length is valid even if one starts with a $1/\sqrt{n}$-consistent estimator other than the MLE, even though traditionally only MLE has been used. This is because only the rate of a $1/\sqrt{n}$-estimator is reflected in the $\log n$ term. In more complicated situations such as the clustering analysis presented in Section 4, more than two stages of coding might be required.

Example 4 (continued) Because $\mathcal{M}_0 = \{N(0,1)\}$ consists of a single distribution, we know from Shannon's Source Coding Theorem that the cost for encoding $x^n = (x_1, \ldots, x_n)$ is

$$L_0(x^n) = \frac{1}{2} \sum_{t=1}^{n} x_t^2 + \frac{n}{2} \log(2\pi).$$

Next, consider encoding x^n via a two-stage scheme based on the class

$$\mathcal{M}_1 = \{N(\theta, 1) : \theta \neq 0\}$$

If we estimate θ by the MLE $\hat{\theta}_n = \bar{x}_n$, the two-stage description length (10) takes the form

$$L_1(x^n) = \frac{1}{2}\sum_{t=1}^{n}(x_t - \bar{x}_n)^2 + \frac{n}{2}\log(2\pi) + \frac{1}{2}\log n. \tag{11}$$

Therefore, following the MDL principle, we choose $\mathcal{M}_0$ over $\mathcal{M}_1$ based on the data string x^n, if

$$|\bar{x}_n| < \sqrt{\log(n)/n}.$$

In this case, the MDL criterion takes the form of a likelihood ratio test whose significance level shrinks to zero as n tends to infinity. □

3.2 Mixture MDL and Stochastic Information Complexity

The mixture form of description length naturally lends itself to theoretical studies of MDL. In Section 5, we highlight connections between this form and both minimax theory and the notion of channel capacity in communication theory (Cover and Thomas, 1991). Since mixture MDL involves integrating over model classes, it can be hard to implement in practice. To get around such difficulties, it can be shown that a first-order approximation to this form coincides with the two-stage MDL criterion derived above. The proof of this fact (Clarke and Barron, 1990) mimics the original derivation of BIC as an approximate Bayesian model selection criterion (Schwarz, 1978, and Kass and Raftery, 1995). An alternative approximation yields yet another form of description length known as Stochastic Information Complexity (SIC). As we will see, mixture MDL shares many formal elements with Bayesian model selection because the underlying analytical tools are the same. However, the philosophies behind each approach are much different. In the next section, we will see how these differences translate into methodology in the context of ordinary linear regression.

The name "mixture" for this form reveals it all. We base our description of a data string x^n on a distribution that is obtained by taking a mixture of the members in the family with respect to a probability density function w on the parameters:

$$m(x^n) = \int f_\theta(x^n) w(\theta) d\theta. \tag{12}$$

Again, we introduce w not as a prior in the Bayesian sense, but rather as a device for creating a distribution for the data based on the model class $\mathcal{M}$. Given a precision δ_d, we follow Section 2.1.2 and obtain the description length

$$-\log m(x^n) = -\log \int f(x_1, \ldots, x_n|\theta) w(\theta) d\theta + n \log \delta_d.$$

Ignoring the constant term, we arrive at

$$-\log \int f(x_1, \ldots, x_n|\theta) w(\theta) d\theta. \tag{13}$$

This integral has a closed form expression when $f(\cdot|\theta)$ is an exponential family and w is a conjugate prior, as was the case in Example 4. When choosing between two models, the mixture form of MDL is equivalent to a Bayes factor (Kass and Raftery, 1995) based on the same priors. A popular method for calculating Bayes factors involves the use of Markov chain Monte Carlo (George and McCulloch, 1997), which can therefore be applied to obtain the description length of mixture codes.

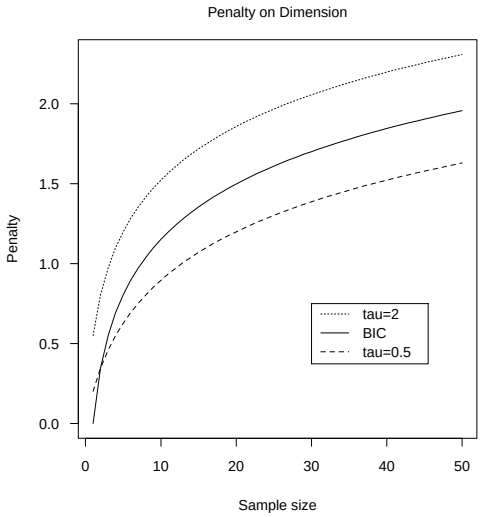

Figure 4: Comparing the penalties imposed by BIC and the mixture form of MDL for $\tau = 0.5$ and $\tau = 2$. The sample size n ranges from 1 to 50.

Example 4 (continued) If we put a Gaussian prior $w = N(0, \tau)$ on the mean parameter θ in $\mathcal{M}_1$ (note that τ is the variance), we find

$$-\log m(x^n) = \frac{n}{2}\log(2\pi) + \frac{1}{2}\log\det(I_n + \tau J_n) + \frac{1}{2}x_n'(I_n + \tau J_n)^{-1}x_n \tag{14}$$

where I_n is the $n \times n$ identity matrix, and J_n is the $n \times n$ matrix of 1's. Simplifying the above expression, we arrive at

$$\frac{1}{2}\sum_t x_t^2 - \frac{1}{2}\frac{n}{1 + 1/(n\tau)}\bar{x}_n^2 + \frac{n}{2}\log(2\pi) + \frac{1}{2}\log(1 + n\tau) \tag{15}$$

Comparing this to the description length for the two-stage encoder (11), we find a difference in the penalty

$$\frac{1}{2}\log(1 + n\tau) \tag{16}$$

which (to first order) is asymptotically the same as that associated with BIC, $\frac{1}{2}\log n$. Depending on the value of the prior variance τ, the quantity (16) represents either a heavier ($\tau > 1$) or a lighter ($\tau < 1$) penalty. In Figure 4 we present a graphical comparison for two values of τ.

□

An analytical approximation to the mixture $m(\cdot)$ in (12) is obtained by Laplace's expansion when w is smooth (Rissanen, 1989). Essentially, we arrive at a two-stage description length which we will call the Stochastic Information Complexity:

$$SIC(x^n) = -\log f(x^n|\hat{\theta}_n) + \frac{1}{2}\log\det(\hat{\Sigma}_n), \tag{17}$$

where $\hat{\theta}_n$ is the MLE and $\hat{\Sigma}_n$ is the Hessian matrix of $-\log f(x^n|\theta)$ evaluated at $\hat{\theta}_n$. For iid observations from a regular parametric family and as $n \to \infty$,

$$\frac{1}{2}\log\det(\hat{\Sigma}_n) = \frac{1}{2}\log\det(nI(\hat{\theta}_n))(1+o(1)) = \frac{k}{2}\log n(1+o(1)). \tag{18}$$

Here, $I(\cdot)$ is the Fisher information matrix of a single observation. The middle term in this chain of equalities,

$$\frac{1}{2}\log\det(nI(\hat{\theta})), \tag{19}$$

can be interpreted as the number of nats needed to encode the k estimated parameter values if we discretize the jth parameter component with a precision $SE(\hat{\theta}_j) = 1/\sqrt{nI_{jj}(\theta)}$ (provided the estimated parameters are either independent or the discretization is done after transforming the parameter space so that the information matrix under the new parameterization is diagonal). It is obviously sensible to take into account the full estimation error when discretizing, and not just the rate. The final equality in (18) tells us that in the limit, SIC is approximately BIC or two-stage MDL. For finite sample sizes, however, SIC's penalty term is usually not as severe as BIC's, and hence in some situations, SIC outperforms BIC. Rissanen (1989, pp. 151, Table 6) illustrates this difference by demonstrating that SIC outperforms two-stage MDL when selecting the order in an AR model with $n = 50$. In Section 4, we will present many more such comparisons in the context of ordinary linear regression.

3.3 Predictive Description Length

Any joint distribution $q(\cdot)$ of $x^n = (x_1, \ldots, x_n)$ can be written in its *predictive form*

$$q(x^n) = \prod_{t=1}^{n} q(x_t|x_1, \ldots, x_{t-1}).$$

Conversely, given a model class $\mathcal{M}$, it is a simple matter to obtain a joint distribution for x^n given a series of predictive distributions. In many statistical models, each of the conditionals $f_\theta(x_j|x_1, \ldots, x_{j-1})$ share the same parameter θ.[8] For iid data generated from a parametric family $\mathcal{M}$, this is clearly the case. Other applications where this property holds include time series, regression and generalized linear models. Suppose that for each t, we form an estimate $\hat{\theta}_{t-1}$ from the first $(t-1)$ elements of x^n. Then, the expression

$$q(x_1, \ldots, x_n) = \prod_t f_{\hat{\theta}_{t-1}}(x_t|x_1, \ldots, x_{t-1}) \tag{20}$$

represents a joint distribution based on the model class $\mathcal{M}$ that is free of unknown parameters. The cost of encoding a data string x^n using (20) is

$$-\log q(x_1, \ldots, x_n) = -\sum_t \log f_{\hat{\theta}_{t-1}}(x_t|x_1, \ldots, x_{t-1}). \tag{21}$$

The MDL model selection criterion based on this form of description is called $PMDL$ for its use of the predictive distribution (20) and PMDL is especially useful for time series models (cf. Hannan and Rissanen, 1982; Hannan, McDougall and Poskitt, 1989; Huang, 1990).

By design, predictive MDL is well suited for time series analysis, where there is a natural ordering of the data; on-line estimation problems in signal processing; and on-line data transmission applications like the binary string example discussed Section 2. At a practical level, under this framework both sender and

[8] Typically, $f(x_1) = f_0(x_1)$ will not depend on θ, however.

receiver start with a pre-determined encoder f_0 to transmit the first data point x_1. This accounts for the leading term in the summation (21). At time t, because the previous $(t-1)$ points are known at each end of the channel, the distribution $f_{\hat{\theta}_{t-1}}(x_t|x_1,\ldots,x_{t-1})$ is also known. This is the tth term in the summation (21). By using the predictive distributions to sequentially update the code, both the encoder and decoder are in effect learning about the true parameter value, and hence can do a better job of coding the data string (provided that one member of the model class actually generated the data).

Example 4 (continued) If we take the initial density f_0 as $N(0,1)$ and set

$$\hat{\theta}_{t-1} = \bar{x}_{t-1} = \sum_{i=1}^{t-1} x_i/(t-1)$$

(with $\bar{x}_0 = 0$) based on $\mathcal{M}_1$, then

$$\begin{aligned} -\log q(x^n) &= -\sum_{t=1}^{n} \log f_{\hat{\theta}_{t-1}}(x_t|x^{t-1}) \\ &= \frac{n}{2}\log(2\pi) + \frac{1}{2}\sum_{t=1}^{n}(x_t - \bar{x}_{t-1})^2. \end{aligned} \tag{22}$$

□

The reasoning we followed in deriving $PMDL$ is identical to the prequential approach to statistics advocated by Dawid (1984, 1991). The form (21) appeared in the literature on Gaussian regression and time series analysis as the *predictive least squares criterion* long before the development of MDL, and early work on $PMDL$ focused mainly on these two applications. The interested reader is referred to Rissanen (1986b), Hemerly and Davis (1989), Hannan and Kavalieris (1984), Hannan, McDougall and Poskitt (1989), Hannan and Rissanen (1982), Gerencsér (1994), Wei (1992), and Speed and Yu (1994). The recent results of Qian, Gabor and Gupta (1996) extend the horizon of this form of MDL to generalized linear models.

In Section 4, we will illustrate the application of $PMDL$ to the (differenced) daily return series studied in Example 3. In this case we will work with the "raw" data rather than the binary up-and-down string treated earlier. Although in special cases such as multinomial the ordering disappears when a Bayes estimator is used for the prediction, in general $PMDL$ depends on a sensible ordering of the data. It is not clear how useful it will be in, say, multivariate regression problems. To get around this problem, Rissanen (1986b) suggests repeatedly permuting the data before applying $PMDL$, and then averaging the predictive code lengths. In Section 4, we avoid these complications and only discuss $PMDL$ in the context of time series data.

3.4 Other Forms of Description Length

The MDL principle offers one the opportunity to develop many other forms of description length, in addition to the three discussed above. In Section 5, we present some of the theoretical validation required for new coding schemes or equivalently new MDL criteria. For example, weighted averages or mixtures of the three common forms will give rise to new description lengths that all achieve the pointwise and minimax lower bounds on redundancy, and hence can all be used for model selection. Further investigation is required to determine how to choose these weights in different modeling contexts.

Recently, Rissanen (1996) developed an MDL criterion based on the normalized maximum likelihood coding scheme of Shtarkov (1987) (cf. Barron et al., 1998). For a flavor of how it was derived, we apply NML (for normalized maximized likelihood) to the binary, DJIA up-and-down indicators introduced in Section 2.

Example 3 (continued) Normalized Maximized Likelihood Coding. As was done in the two-stage scheme, we first transmit k. Then, both sender and receiver know that the indicator sequence must be among the collection of strings of size n with exactly k 1's. This group of sequences is known as the *type class* $T(n,k)$. Under the iid Bernoulli model, each string in the type class is equally likely, and we can employ a uniform code on $T(n,k)$ for communicating its elements. When applied to the return string, the NML code requires $\log_2 \frac{n!}{k!(n-k)!}$ or 6421 bits, giving us a total code length of 6434 bits when we add the cost of encoding k. This represents a saving of 7 bits over the two-stage encoder described in Section 2, where x^n was transmitted using an iid Bernoulli encoder with $\hat{p}_n = k/n$ in the second stage. □

In general, the NML description of a data string works by restricting the second stage of coding to a data region identified by the parameter estimate. In the example above, this meant coding the return string as an element of $T(n,k)$ rather than $\{0,1\}^n$. Rissanen (1996) formally introduces this scheme for MDL model selection, and discusses its connection with minimax theory. We will see another application of this code when we take up ordinary linear regression in the next section.

4 Applications of MDL in Model Selection

4.1 Linear Regression Models

Regression analysis is a tool to investigate the dependence of a random variable y on a collection of potential predictors $x_1, \ldots, x_M$. Associate with each predictor x_m a binary variable, γ_m, and consider models given by

$$y = \sum_{\gamma_m = 1} \beta_m x_m + \epsilon, \tag{23}$$

where ϵ has a Gaussian distribution with mean zero and unknown variance σ^2. The vector $\gamma = (\gamma_1, \ldots, \gamma_M) \in \{0,1\}^M$ will be used as a simple index for the 2^M possible models given by (23). Let β_γ and X_γ denote the vector of coefficients and the design matrix associated with those variables x_m for which $\gamma_m = 1$. In this section, we apply MDL to the problem of model selection, or equivalently, the problem of identifying one or more vectors γ that yield the "best" or "nearly best" models for y in equation (23). In many cases, not all of the 2^M possibilities make sense, and hence our search might be confined to only a subset of index vectors γ.

The concept of "best," or more precisely the measure by which we compare the performance of different selection criteria, is open to debate. Theoretical studies, for example, have examined procedures in terms of either consistency (in the sense that we select a "true" model with high probability) or prediction accuracy (providing small mean squared error), and different criteria can be recommended depending on the chosen framework. Ultimately, no matter how we settle the notion of "best," the benefit of a selection rule is derived from the insights it provides into real problems. Mallows (1973) puts it succinctly: "The greatest value of the device [model selection] is that it helps the statistician to examine some aspects of the structure of his data and helps him to recognize the ambiguities that confront him." In general, we should apply any selection procedure with some care, examining the structure of several good-fitting models rather than restricting our attention to a single "best." This point tends to be lost in simulation studies that necessitate blunt optimization of the criterion being examined. At the end of this section, we present two applications that illustrate different practical aspects of model selection for regression analysis. The first involves the identification of genetic loci associated with the inheritance of a given trait in fruit flies. Here, MDL aids in evaluating specific scientific hypotheses. In the second example, we construct efficient representations for a

large collection of hyperspectral (curve) data collected from common supermarket produce. Model selection is used in this context as a tool for data (dimension) reduction prior to an application of (MDL-like) cluster analysis.

Our review of regression problems draws from number of sources on MDL (see Rissanen, 1987 and 1989; Speed and Yu, 1993; and Barron et al, 1998) as well as the literature on Bayesian variable selection (see Smith and Spiegelhalter, 1980; O'Hagan, 1994; Kass and Raftery, 1995; and George and McCulloch, 1997). Because the need for selection in this context arises frequently in applications, we will derive several MDL criteria in detail.

4.1.1 Several Forms of MDL for Regression

Following the general recipe given in the previous sections, the MDL criteria we derive for regression can all be written as a sum of two code lengths

$$L(y|X_\gamma, \gamma) + L(\gamma)\,. \tag{24}$$

This two-stage approach (see Section 3.1) explicitly combines both the cost to encode the observed data y using a given model γ, as well as the cost to transmit our choice of model. For the second term, we use the Bernoulli($\frac{1}{2}$) model discussed in Section 2.2 to describe the elements of γ; that is, the γ_m are taken to be independent, binary random variables and the probability that $\gamma_m = 1$ is a half. Following this approach, each value of γ has the same probability

$$P(\gamma) = \left(\frac{1}{2}\right)^k \left(\frac{1}{2}\right)^{M-k} = \left(\frac{1}{2}\right)^M . \tag{25}$$

Therefore, the cost $L(\gamma) = -\log P(\gamma)$ is constant. When we have reason to believe that smaller or larger models are preferable, a different Bernoulli model (with a smaller or larger value of p) can be used to encode γ. This approach has been taken in the context of Bayesian model selection and is discussed at the end of this section.

Having settled on this component in the code length, we turn our attention to the first term in (24), the cost of encoding the data, $L(y|X_\gamma, \gamma)$. In the next few pages, we will describe different MDL schemes for computing this quantity. To simplify notation, we will drop the dependence on model index: pick a vector γ and let $\beta = \beta_\gamma$ denote the $k = k_\gamma$ coefficients in (23) for which $\gamma_m = 1$. Similarly, let $X = X_\gamma$ be the design matrix associated with the selected variables in γ. For the most part, we will work with maximum likelihood estimates for both the regression coefficients β (also known as ordinary least squares or OLS estimates) and the noise variance σ^2,

$$\hat{\beta} = (X'X)^{-1}X'y \quad \text{and} \quad \hat{\sigma}^2 = \|y - X\hat{\beta}\|^2/n\,. \tag{26}$$

Finally, we take RSS to represent the residual sum of squares corresponding to this choice of $\hat{\beta}$.

Two-stage MDL Recall from Section 3.1 that two-stage MDL for a parametric model class is equivalent to the BIC criterion. Using the linear regression model (23), the code length associated with the observed data y is then given by the familiar forms

$$\frac{1}{2\sigma^2} RSS + \frac{k}{2}\log n\,, \tag{27}$$

when σ^2 is known, and

$$\frac{n}{2}\log RSS + \frac{k}{2}\log n\,. \tag{28}$$

when it is unknown. To derive these expressions, we have applied the formula (10) using the estimators (26) and dropping constants that do not depend on our choice of model.

In both cases, the penalty applied to the dimension k depends on the sample size n. Related criteria like Mallows' C_p (Mallows, 1973) and Akaike's AIC (Akaike, 1974) differ only in the size of this penalty:

$$C_p = \frac{1}{2\sigma^2} RSS + k \qquad \text{and} \qquad AIC = \frac{n}{2} \log RSS + k, \tag{29}$$

where we have again ignored terms that do not depend on our choice of model.[9] While keeping the general form of these criteria, various authors have suggested other multipliers in front of k that can offer improved performance in special cases: see Sugiura (1978) and Hurvich and Tsai (1989) for a corrected version of AIC for small samples; Hurvich, Simonoff and Tsai (1998) for AIC in nonparametric regression; and Mallows (1995) for an interpretation of C_p when a different value of the penalty on model size is desired. Shortly, we will present an application in which a multiple of the BIC penalty is proposed as the "correct" cost for a particular class of problems arising in genetics.

Mixture MDL and SIC. In Section 3.2 we formally introduced the use of mixture distributions for constructing valid description lengths based on parametric classes. As this form of MDL is structurally similar to a Bayesian analysis, our discussion of mixture MDL for regression problems will be relatively brief and borrow heavily from a classical treatment of Bayesian variable selection for linear models. The framework for applying mixture codes in this context can be found in Rissanen (1989).

Under the regression set-up, we form a mixture distribution for y (conditional on our choice of model and the values of the predictors X) by introducing a density function $w(\beta, \sigma^2)$,

$$m(y|X) = \int f(y|X, \beta, \tau)\ w(\beta, \tau)\, d\beta\, d\tau\,. \tag{30}$$

To obtain a closed-form expression for $m(y|X)$, Rissanen (1989) takes w to be a member of the natural conjugate family of priors for the normal linear regression model (23); namely the so-called normal-inverse-gamma distributions (see the appendix). Under this density, the noise variance σ^2 is assigned an inverse-gamma distribution with shape parameter a. Then, conditional on σ^2, the coefficients β have a normal distribution with mean zero and variance-covariance matrix $\frac{\sigma^2}{c}\Sigma$, where Σ is a known, positive definite matrix. In his original derivation, Rissanen (1989) selects Σ to be the $k \times k$ identity matrix. Sidestepping this decision for the moment, the mixture code length for y computed from (13) is given by

$$\begin{aligned} -\log\, m(y|X) &= -\log\, m(y|X, a, c) \\ &= -\frac{1}{2}\log|c\Sigma^{-1}| + \frac{1}{2}\log\left|c\Sigma^{-1} + X^tX\right| - \frac{1}{2}\log a + \frac{n+1}{2}\log\left(a + R_c\right)\,, \end{aligned} \tag{31}$$

where

$$R_c \;=\; R_c \;=\; y^ty \;-\; y^tX\left(c\Sigma^{-1} + X^tX\right)^{-1}X^ty\,.$$

In expression (31), we have made explicit the dependence of the mixture code length on the values of two hyperparameters in the density w: a, the shape parameter of the inverse-gamma distribution for σ^2, and c, the (inverse) scale factor for β.

Rissanen (1989) addresses the issue of hyperparameters by picking a and c to minimize the quantity (31) model by model. It is not difficult to see that $\hat{a} = R_c/n$, while for most values of Σ, $\hat{c}$ must be found

[9] The form of C_p given above applies when σ^2 is known. If not, Mallows (1973) suggests using an unbiased estimate $\widehat{\sigma}^2$.

numerically. An algorithm for doing this is given in the appendix. Treating a and c in this way, however, we lose the interpretation of $-\log m(y|X,\hat{a},\hat{c})$ as a description length. To remain faithful to the coding framework, the optimized hyperparameter values $\hat{a}$ and $\hat{c}$ must also be transmitted as overhead. Explicitly accounting for these extra factors gives us the mixture code length

$$-\log m(y|X,\hat{a},\hat{c}) \;+\; L(\hat{a}) \;+\; L(\hat{c})\;. \tag{32}$$

Because $\hat{a}$ and $\hat{c}$ are determined by maximizing the (mixture or marginal) log-likelihood (31), they can be seen to estimate a and c at the standard parametric rate of $1/\sqrt{n}$. Therefore, we take a two-stage approach to coding $\hat{a}$ and $\hat{c}$ and assign each a cost of $\frac{1}{2}\log n$ bits. Rissanen (1989) argues that no matter how we account for the hyperparameters, their contribution to the overall code length should be small. This reasoning is borne out in our simulation studies. At the end of this section we return to the issue of coding hyperparameters and discuss reasonable alternatives to the two-stage procedure motivated here.

An important ingredient in our code length (32) is the prior variance-covariance matrix, Σ. As mentioned above, for most values of Σ we cannot find a closed-form expression for $\hat{c}$ and must instead rely on an iterative scheme. (A general form for the procedure is outlined in the appendix.) Rissanen (1989) gives details for the special case $\Sigma = I_{k\times k}$. We refer to the criterion derived under this specification as $iMDL$, where i refers to its use of the identity matrix. In the Bayesian literature on linear models, several authors have suggested a computationally attractive choice for Σ; namely $\Sigma = (X^tX)^{-1}$. Zellner (1986) christens this specification the g-prior. In our context, this value of Σ provides us with a closed-form expression for $\hat{c}$. After substituting $\hat{a} = R_c/n$ for a in (31), it is easy to see that

$$1/\hat{c} = \max(F-1,0) \quad \text{with} \quad F = \frac{(y'y - RSS)}{kS}\,, \tag{33}$$

where F is the usual F-ratio for testing the hypothesis that each element of β is zero, and $S = RSS/(n-k)$. The computations are spelled out in more detail in the appendix. The truncation at zero in (33) rules out negative values of the prior variance. Rewriting (33), we find that $\hat{c}$ is zero unless $R^2 > k/n$, where R^2 is the usual squared multiple correlation coefficient. When the value of $\hat{c}$ is zero, the prior on β becomes a point mass at zero, effectively producing the "null" mixture model[10] corresponding to $\gamma = (0,\ldots,0)$. Substituting the optimal value of $\hat{c}$ into (31) and adding the cost to code the hyperparameters as in (32), we arrive at a final mixture form

$$gMDL \;=\; \begin{cases} \frac{n}{2}\log S + \frac{k}{2}\log F + \log n\,, & R^2 \geq k/n \\ \frac{n}{2}\log\left(\frac{y'y}{n}\right) + \frac{1}{2}\log n\,, & \text{otherwise}\,. \end{cases} \tag{34}$$

which we will refer to as $gMDL$ for its use of the g-prior. From this expression, we have dropped a single bit that is required to indicate whether the condition $R^2 < k/n$ is satisfied and hence which model was used to code the data. When $R^2 < k/n$, we apply the null model which does not require communicating the hyperparameter $\hat{c}$. Hence a $\frac{1}{2}\log n$ term is missing from the lower expression.

Unlike most choices for Σ, the $g-$prior structure provides us with an explicit criterion that we can study theoretically. First, since $n/n = 1 \geq R^2$, this version of mixture MDL can never choose a model with dimension larger than the number of observations. After a little algebra, it is also clear that $gMDL$ orders models of the same dimension according to RSS; that is, holding k fixed, the criterion (34) is an increasing function of RSS. This property is clearly shared by AIC, BIC and C_p. Unlike these criteria, however, $gMDL$ applies an adaptively determined penalty on model size. Rewriting (34) in the form

$$\frac{n}{2}\log RSS + \frac{\alpha}{2}k \tag{35}$$

[10] The null model is a scale mixture of normals, each $N(0,\tau)$ and τ having an inverse-gamma prior.

we find that α depends on the F-statistics, so that "poor fitting" models receive a larger penalty.

Finally, in Section 3.2, we applied a simple approximation to the mixture form of MDL to derive the so-called Stochastic Information Complexity (17). For a model index γ, the Hessian matrix of the mixture $m(\cdot)$ in (12) based on the $k+1$ parameters β and $\tau = \sigma^2$ is given by

$$\begin{pmatrix} \frac{1}{\hat{\tau}} X'X & 0 \\ 0 & \frac{n}{2\hat{\tau}^2} \end{pmatrix}.$$

Therefore, a little algebra reveals the SIC criterion

$$SIC(\gamma) = \frac{n-k-2}{2} \log RSS + \frac{k}{2} \log n + \frac{1}{2} \log \det[X'X], \tag{36}$$

where we have omitted an additive constant that is independent of model choice.

Normalized Maximized Likelihood As mentioned in Section 3.4, the normalized maximum likelihood form of MDL (cf. Rissanen, 1996, and Barron et al., 1998) is very recent and only some of its theoretical properties are known. It is motivated by the maximum likelihood code introduced by Shtarkov (1987). Recall that the maximum likelihood estimates of β and $\tau = \sigma^2$ are given by (26). Let $f(y|X, \beta, \tau)$ be the joint Gaussian density of the observed data y, so that the normalized maximum likelihood function is

$$\hat{f}(y) = \frac{f(y|X, \hat{\beta}(y), \hat{\tau}(y))}{\int_{\mathcal{Y}(r,\tau_0)} f(z|X, \hat{\beta}(z), \hat{\tau}(z)) dz}, \tag{37}$$

where $\mathcal{Y}(r, \tau_0) = \{z | \hat{\beta}'(z) X'X \hat{\beta}(z)/n \leq r, \hat{\tau}(z) \geq \tau_0\}$. In this case, the maximized likelihood is not integrable, and our solution is to simply restrict the domain of $\hat{f}$ to $\mathcal{Y}$. Recall that we did not encounter this difficulty with the Bernoulli model studied in Section 3.4; where given the number of 1's, the binary sequences had a uniform distribution over the type class. Using the sufficiency and independence of $\hat{\beta}(y)$ and $\hat{\tau}(y)$, one obtains

$$-\log \hat{f}(y) = \frac{n}{2} \log RSS - \log, \left(\frac{n-k}{2}\right) - \log, \left(\frac{k}{2}\right) + \frac{k}{2} \log \frac{r}{\tau_0} - 2\log(2k). \tag{38}$$

To eliminate the hyper-parameters r and τ_0, we again minimize the above code length for each model by setting

$$\hat{r} = \frac{\hat{\beta}'(y) X'X \hat{\beta}(y)}{n} = \frac{y'y - RSS}{n} \quad \text{and} \quad \hat{\tau}_0 = \frac{RSS}{n}.$$

By substituting these values for r and τ_0 into (38), we obtain the selection criteria $nMDL$ (n for "normalized maximum likelihood"),

$$nMDL = \frac{n}{2} \log RSS - \log, \left(\frac{n-k}{2}\right) - \log, \left(\frac{k}{2}\right) + \frac{k}{2} \log \frac{y'y - RSS}{RSS} - 2\log(2k). \tag{39}$$

Technically, we should also add $\frac{1}{2} \log n$ for each of the optimized hyperparameters as we had done for $gMDL$. In this case, the extra cost is common to all models and can be dropped. Rewriting this expression, we find that

$$\begin{aligned} nMDL &= \frac{n}{2} \log S + \frac{k}{2} \log F \\ &\quad + \frac{n-k}{2} \log(n-k) - \log, \left(\frac{n-k}{2}\right) + \frac{k}{2} \log(k) - \log, \left(\frac{k}{2}\right) - 2\log k, \end{aligned}$$

up to an additive constant that is independent of k. Applying Stirling's approximation to each , $(\cdot)$ yields

$$nMDL \approx \frac{n}{2}\log S + \frac{k}{2}\log F + \frac{1}{2}\log(n-k) - \frac{3}{2}\log k\,.$$

We recognize the leading two terms in this expression as the value of $gMDL$ (34) when $R^2 > k/n$. This structural similarity is interesting given that these two MDL forms were derived from very different codes.

Our derivation of $nMDL$ follows Barron et al. (1998) who remedy the non-integrability of the maximized likelihood by restricting $\hat{f}$ to the bounded region $\mathcal{Y}$. Recently, Rissanen (2000) addressed this problem by applying another level of normalization. Essentially, the idea is to treat the hyperparameters τ_0 and r as we did β and τ. The maximized likelihood (39) is normalized again, this time with respect to $\hat{\tau}_0 = \hat{\tau}_0(y)$ and $\hat{r} = \hat{r}(y)$. Following a straightforward conditioning argument, Rissanen (2000) finds that this second normalization makes the effect of the hyperparameters on the resulting code length additive, and hence can be ignored for model selection.[11] Ultimately, the final NML criterion derived in this way differs from our $nMDL$ rule in (39) by only an extra $\log k$. Rissanen (2000) applies his NML selection criterion to wavelet denoising, illustrating its performance on a speech signal.

Stine and Foster (1999) also explore the derivation of NML for estimating the location parameter in a 1-dimensional Gaussian family, but propose a different solution to the non-integrability problem. They suggest a numerically-derived form which is shown to have a certain minimax optimality property (up to a constant factor). In general, the derivation of NML in such settings is still very much an area of active research. We present $nMDL$ here mainly to illustrate the reasoning behind this form, and comment on its similarity to $gMDL$.

Discussion As mentioned at the beginning of this section, there are alternatives to our use of the Bernoulli($\frac{1}{2}$) model for coding the index γ. For example, George and Foster (1999) take the elements of γ to be *a priori* independent Bernoulli random variables with success probability p. They then select a value for p by maximum likelihood (in the same way we treated the parameters a and c). In early applications of model selection to wavelet expansions, the value of p was fixed at some value less than a half to encourage small models (Clyde, Parmigiani and Vidakovic, 1998).

The use of a normal-inverse-gamma prior with $\Sigma = (X^tX)^{-1}$ appears several times in the literature in Bayesian model selection. For example, Akaike (1977) essentially derives $gMDL$ for orthogonal designs. Smith and Spiegelhalter (1980) use this prior when considering model selection based on Bayes factors where $a = 0$ and $c = c(n)$ is a deterministic function of sample size. These authors were motivated by a "calibration" between Bayes factors and penalized selection criteria in the form of BIC and AIC (see also Smith, 1996; and Smith and Kohn, 1996). Finally, Peterson (1986) builds on the work of Smith and Spiegelhalter (1980) by first choosing $\Sigma = (X^tX)^{-1}$ and then suggesting that c be estimated via (marginal) maximum-likelihood based on the same mixture (31). This is essentially Rissanen's (1989) prescription.

Throughout our development of the various MDL criteria, we have avoided the topic of estimating the coefficient vector β once the model has been selected. In the case of AIC and BIC, it is common practice to simply rely on OLS. The resemblance of mixture MDL to Bayesian schemes, however, suggests that for this form a shrinkage estimator might be more natural. For example, the criterion $gMDL$ is implicitly comparing models not based on $\hat{\beta}$, but rather the posterior mean (conditional on our choice of model)

$$\max\left(1 - \frac{1}{F}\,,\,0\right)\hat{\beta}$$

[11] In deriving his form of NML, Rissanen (2000) also handles the issue of coding the model index γ differently than we have in (24). Another normalization is applied, this time across a set of model indices Ω.

associated with the normal-inverse-gamma prior and the regression model (23). Here, F is defined as in the $gMDL$ criterion (34). Recall that the condition that $F > 1$ is equivalent to the multiple R^2 being larger than k/n. Interestingly, this type of shrinkage estimator was studied by Sclove (1968) and Sclove, Morris and Radhakrishnan (1972), where it was shown to have improved mean squared error performance over OLS and other shrinkage estimators. In the case of $iMDL$, the coefficient vector β is estimated via classical ridge regression. Of course, Bayesian methods can be applied more generally within the MDL framework. For example, in Section 3.1 we found that any $\sqrt{n}-$consistent estimator can be used in the two-stage coding scheme. This means that we could even substitute Bayesian estimators for σ^2 and β in the two-stage criterion (28) rather than $\hat{\beta}$ and $\hat{\sigma}^2$. The beauty of MDL is that each such scheme can be compared objectively, regardless of its Bayesian or frequentist origins.

Next, in several places we are forced to deal with hyperparameters that need to be transmitted so that the decoder knows which model to use when reconstructing the data y. We have taken a two-stage approach, attaching a fixed cost of $\frac{1}{2}\log n$ to each such parameter. Rissanen (1989) proposes using the universal prior on integers L^* after discretizing range of the hyperparameters in a model-independent way. If prior knowledge suggests a particular distribution, then naturally it should be used instead. In general, the value of the hyperparameters are chosen to minimize the combined code length

$$(\,\hat{a},\hat{c}\,) = \min_{(a,c)} \{L(y|X,a,c) + L(a) + L(c)\} \tag{40}$$

where the first term represents the cost of coding the data given the value of the hyperparameters, $\hat{a}$ and $\hat{c}$, and the second term accounts for the overhead in sending them. In our derivation of $iMDL$ and $gMDL$, we took the latter terms to be constant so that we essentially selected the hyperparameters via maximum (mixture or marginal) likelihood. In the simulation study presented in the next section, each reasonable method for incorporating the cost of the hyperparameters produced selection criteria with similar prediction errors. As a final note, the theoretical material in Section 5 justifies the use of MDL *only* when the values of the hyperparameters are fixed. The minimization in (40) complicates a general analysis, but certainly selection rules can be studied on a case-by-case basis when explicit forms appear (as in the case of $gMDL$). We leave a detailed discussion of this material to a future paper.

4.1.2 A Simulation Study

When choosing between models with the same number of variables, AIC and each of the MDL procedures BIC, $gMDL$ and $nMDL$ select the model with the smallest residual sum of squares, RSS. Therefore, to implement these criteria, it is sufficient to consider only the lowest RSS models for dimensions $1, 2, \ldots, M$. When the number of predictors is relatively small (say, less than 30), it is not unreasonable to perform an exhaustive search for these models by a routine branch-and-bound algorithm (see Furnival and Wilson, 1974, for a classic example). Unfortunately, the criteria $iMDL$ and SIC involve characteristics of the design matrix X, requiring a different technique. An obvious (and popular) choice involves greedy, stepwise model building. In this case, some combination of stepwise addition (sequentially adding new variables that create the largest drop in the model selection criterion) and deletion (removing variables that have the least impact on the criterion) can be used to identify a reasonably good collection of predictors. Rissanen (1989) discusses these greedy algorithms in the context of (approximately) minimizing $iMDL$ or SIC. The recent interest in Bayesian computing has produced a number of powerful McMC schemes for variable selection. To apply these ideas to MDL, first recall that the mixture form is based on an integrated likelihood (12) that we can write as $m(y) = p(y|\gamma)$ for model indices γ. Assuming that each $\gamma \in \{0,1\}^M$ is equally likely a priori, we find that

$$m(y) = p(y|\gamma) \propto p(\gamma|y)\,,$$

	Criterion	Median model error	Average model size	Proportion correct	Equivalent penalty

Table 1: Simulation results for $n = 20$ observations from model (41). In each case, $\rho = 0.5$ and $\sigma = 4$.

a posterior distribution over the collection of possible models. Candidate chains for exploring this space include the Gibbs sampler of George and McCulloch (1993); the importance sampler of Clyde, DeSimone and Parmigiani (1996), applicable when the predictor variables are orthogonal; and the Occam's window scheme of Madigan, Raftery and Hoeting (1997). In the simulation study described below, however, the number of covariates is small, so that we could simply evaluate SIC and $iMDL$ on *all* possible models to identify the best.

To understand the characteristics of each MDL criterion, we consider three simulated examples. These have been adapted from similar experiments in Tibshirani (1996) and Fourdrinier and Wells (1998). In each case, we work with data sets consisting of 20 observations from a model of the form

$$y = x\beta + \sigma\epsilon, \tag{41}$$

where $x \in \mathbb{R}^8$ has a multivariate normal distribution with mean zero and variance-covariance matrix $V_{ij} = 2\rho^{|i-j|}$, $i, j = 1, \ldots, 8$; and ϵ is an independent standard normal noise term. In Table 1, we compare several MDL selection criteria across 100 data sets simulated according to (41), where $\rho = 0.5$, $\sigma = 4$ and $\beta \in \mathbb{R}^8$ is assigned one of three (vector) values listed in Table 1. We quote both the average size of models selected by

each criteria as well as the median model error, where model error is defined to be

$$E\{x\hat{\beta} - x\beta\}^2 = (\hat{\beta} - \beta)'V(\hat{\beta} - \beta)\,,$$

with $\hat{\beta}$ obtained by an ordinary least squares (OLS) fit with the selected variables. In Table 1 we have also included the signal-to-noise (snr) ratio for each set of simulations, where we take

$$\text{snr} = \beta' V \beta / \sigma^2\,.$$

The row labeled OLS represents a straight OLS fit to the complete set of variables.

In this simulation, we initially compared AIC, BIC, $gMDL$, SIC, and $nMDL$. An anonymous referee suggested that as AIC is based on large-sample approximations, a modified criterion AIC_C is a more appropriate comparison. This form was derived by Sugiura (1978) for use in small samples and was later studied by Hurvich and Tsai (1989). In our notation, this criterion is given by

$$AIC_C = \frac{n}{2}\log RSS + \frac{n}{2}\frac{1 + k/n}{1 - (k+2)/n}$$

It is well known that when the data-generating mechanism is infinite dimensional (and includes the candidate covariate variables), AIC is an optimal selection rule in terms of prediction error; that is, AIC identifies a finite dimensional model that, while an approximation to the truth, has good prediction properties. However, when the underlying model is in fact finite dimensional (the truth belongs to one of the model classes being evaluated), AIC tends to choose models that are too large. The criterion AIC_C was derived under the assumption of a finite truth, and avoids the asymptotic arguments used in the original derivation of AIC. Computationally, this criterion is also amenable to the branch and bound techniques mentioned above.

In general, except for SIC, the MDL criteria outperformed AIC, AIC_C and BIC. Notice that AIC_C does improve over AIC in all but the case of entirely weak effects, and even here the difference is small. This improvement is to be expected as the data-generating model is among the candidates being evaluated, precisely the finite dimensional set-up under which AIC_C was derived. The selection rule $iMDL$, seems to perform exceedingly well in each simulation set-up, although its performance degrades slightly when we considered larger sample sizes. In only one of the simulation suites did $gMDL$ perform poorly relative to the other MDL schemes, namely the third case with entirely weak effects. When we increase the sample size to 50, but maintain the same signal-to-noise ratio, $gMDL$ recovers and its model error rivals that of $iMDL$. Another interesting effect to mention in Table 1 is that in the third case (weak effects), model selection with $iMDL$ out-performs OLS and AIC. In principle, AIC is known to work well in this situation. When we re-ran these simulations with $\rho = 0$, corresponding to independent predictors, AIC did in fact improve to the level of $iMDL$. The implicit shrinkage performed by $iMDL$ when evaluating models through (32) is apparently responsible for $iMDL$'s excellent performance here. We hasten to add, however, that in all cases, once a model is selected, we are simply performing an OLS fit to obtain $\hat{\beta}$ (from which the model error is derived). For both mixture forms of MDL and for all the simulations, the shrinkage procedures based on $\hat{c}$ improve on these OLS estimates.

Given the penalties on k imposed by AIC and BIC, one can expect that AIC will favor larger models while BIC is more conservative. This can be seen in each of our simulation results. The MDL forms, however, can be thought of as imposing an adaptive penalty on model size. For comparison purposes, we computed an *equivalent* penalty in a neighborhood of the best model identified by the MDL criteria. To be more precise, in Figure 4 we plot the $iMDL$ criterion versus model size, evaluated for the $2^8 = 512$ possible models using data from a single run of the simulation described above. Define $iMDL^*(k)$ to be the minimum value of $iMDL$ among all models of size k and let $RSS^*(k)$ be the residual sum of squares for that model. Then, consider the quantity

$$\lambda(k) = 2\left[iMDL^*(k) - \frac{n}{2}\log RSS^*(k)\right]\,.$$

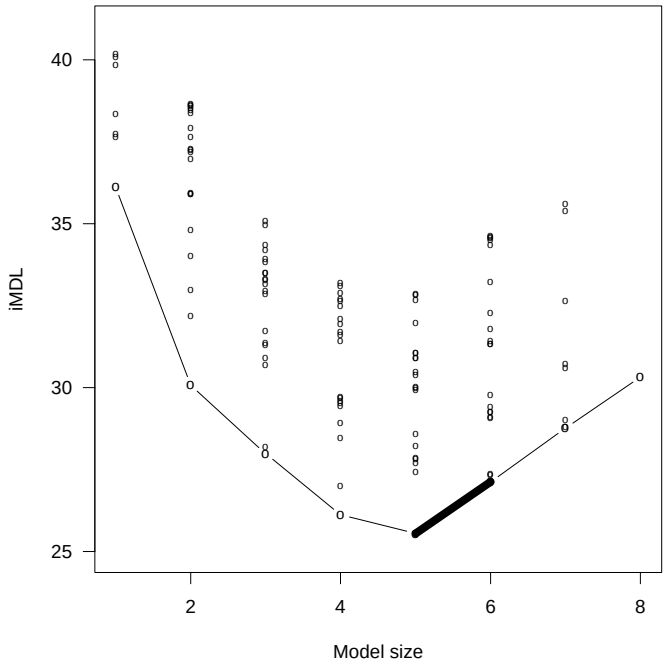

Figure 5: Calculating an equivalent penalty for the MDL criteria. In this case, we consider $iMDL$ and restrict our attention to a difference of the two points connected by heavy black segments.

If we replaced $iMDL$ with either AIC or BIC in this definition, then the difference $\lambda(k+1) - \lambda(k)$ would be 2 or $\log n$, respectively.[12] To get a rough idea of the price placed on dimension by the MDL criteria, we looked at this difference in the neighborhood of the minimum. In Figure 4, the heavy, black line joins the two points used to evaluate $\lambda(k)$. The average equivalent penalty across the 100 replicates of each simulation is given in Table 1. The adaptability of these procedures is immediately evident from the first and third simulation set-ups. When faced with a single, strong effect, for example, the penalties associated with $iMDL$ and $gMDL$ are larger than that of BIC, forcing smaller models; while when given a number of small effects, the penalty shrinks below that for AIC allowing $iMDL$ to capture larger models. The criterion SIC tends to impose a penalty that is much weaker than AIC, leading to its discouraging results.

From these simulations, we find that there is a distinct performance advantage in the adaptive forms of MDL, $gMDL$ and $iMDL$, over BIC, AIC, and AIC_C in model selection. The theoretical properties of $gMDL$ and $iMDL$ are currently under study (Hansen and Yu, 1999). Interestingly, both of these forms share much in common with the new empirical Bayes criteria of George and Foster (1998) and the *Peel* method of Fourdrinier and Wells (1998). In the next section, we investigate the use of MDL in two applied problems. In the first case, a hand-crafted procedure has been proposed to perform model selection within a restricted class of problems. We find that the adaptivity of MDL produces results that are (automatically) equivalent to this specialized approach. In the second example, we apply MDL to curve estimation. The output from this procedure will be used later to illustrate a form of MDL for cluster analysis.

[12] While the expressions for BIC and AIC can be manipulated in other ways to tease out the penalty on dimension, we have chosen differences because most of the MDL expressions are only known up to additive constants.

4.1.3 Applying MDL in Practice: Two Regression Examples

The genetics of a fruit fly. Our first example comes from genetics and has been developed into a variable selection problem by Cowen (1989), Doerge and Churchill (1996) and Broman (1997). The data we consider were collected by Long, Mullaney, Reid, Fry, Langley and Mackay (1995) as part of an experiment to identify *genetic loci*, locations on chromosomes, that influence the number of bristles on the fruit fly *Drosophila melanogaster*.

The experimental procedure followed by Long et al. (1995) was somewhat complicated, but we will attempt to distill the essential features. First, a sample of fruit flies were selectively inbred to produce two family lines differentiated on the basis of their abdominal bristles. Those flies with low bristle counts were separated into one parental line L, while those with high counts formed another line H. Several generations of flies were then obtained from these two populations through a *backcross*. That is, the H and L lines were crossed to yield the so-called first filial generation F_1, and then the F_1 flies were again crossed with the low parental line L. Ultimately, sixty-six inbred family lines were obtained in this way so that the individual flies within each group were genetically identical at nineteen chosen genetic markers (or known locations on the chromosomes). Abdominal bristle counts were collected from a sample of 20 males and 20 females from each of these populations. By design, all the flies bred in the backcross inherited one chromosome from the first filial generation F_1 and one from the low parental line L, so that at each of the genetic markers they have either the LL or HL genotype. The goal of this experiment was to identify whether the genotype at any of the nineteen genetic markers influenced observed abdominal bristle counts.

Let y_{ij}, $i = 1, \ldots, 66$, $j = 1, 2$, denote the average number of bristles for line i, tabulated separately for males, corresponding to $j = 1$, and females, corresponding to $j = 2$. Consider a model of the form

$$y_{ij} = \mu + \alpha s_j + \sum_l \beta_l x_{il} + \sum_l \delta_l s_j x_{il} + \epsilon_{ij} \tag{42}$$

where s_j is a contrast for sex, $s_1 = -1$ and $s_2 = +1$; and $x_{il} = -1$ or $+1$ according to whether line i had genotype LL or HL at the lth marker, $l = 1, \ldots, 19$. Therefore, the full model (42) includes main effects for sex and genotype as well as the complete sex $\times$ genotype interaction, a total of 39 variables. The error term ϵ_{ij} is taken to be Gaussian with mean zero and unknown variance σ^2. In this framework, identifying genetic markers that have an influence on bristle counts becomes a problem of selecting genotype contrasts in the model (42). Following Broman (1997), we do not impose any hierarchical constraints on our choice of models, so that any collection of main effects and interactions can be considered. Therefore, in the notation of Section 4.1 we introduce an index vector $\gamma \in \{0,1\}^{39}$ that determines which covariates in (42) are active (we have intentionally excluded the intercept from this index, forcing it to be in each model).

Broman (1997) considered variable selection for this problem with a modified BIC criterion

$$BIC_\eta = \frac{n}{2} \log RSS + \eta \frac{k}{2} \log n, \tag{43}$$

where $\eta = 2$, 2.5, or 3. Broman (1997) found that placing a greater weight on the dimension penalty $\log(n)/2$ is necessary in this context to avoid including spurious markers. As with the data from Long et al. (1995), model selection is complicated by the fact that the number of cases n collected for backcross experiments is typically a modest multiple of the number of possible predictor variables. Aside from practical considerations, Broman (1997) motivated (43) by appealing to the framework in Smith (1996) and Smith and Kohn (1996). These authors start with the mixture distribution (31) derived in Section 4.1.1, taking the improper prior specification $a = d = 0$ in (63) and (64). Instead of finding optimal values for c, they consider deterministic functions $c = c(n)$. This approach was also taken by Smith and Spielgelhalter (1980) who attempted to calibrate Bayesian analyses with other selection criteria like AIC. If we set $c(n) = n^\eta$ for all models, then

from (31) we roughly obtain Broman's criterion (43).[13] The larger we make η, the more diffuse our prior on β becomes. Because the same scaling factor appears in the prior specification for models of different dimensions, the mass in the posterior distribution tends to concentrate on models with fewer terms.

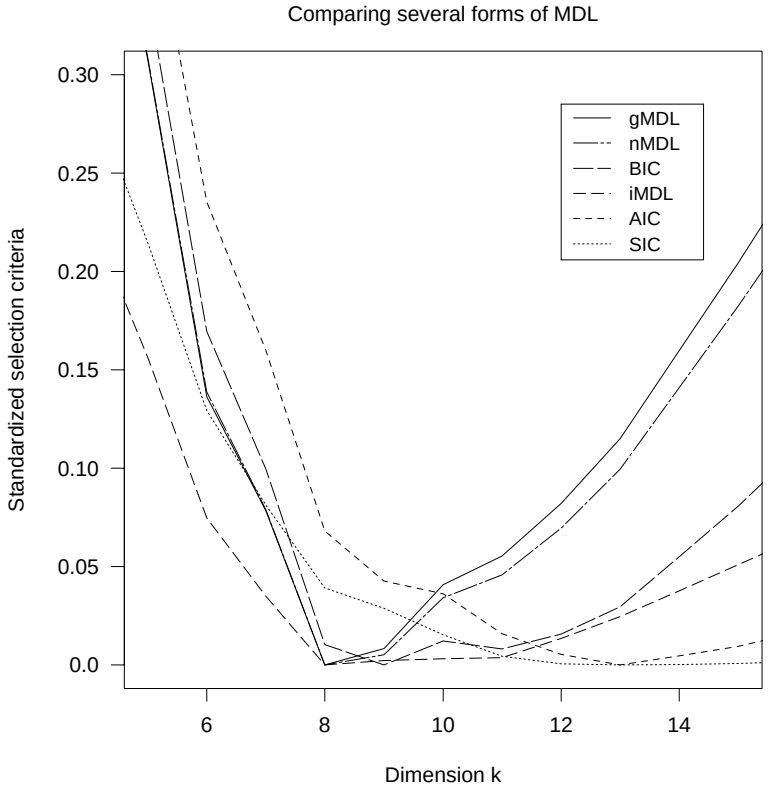

Figure 6: Comparing several different model selection criteria.

As the number of markers studied by Long et al. (1997) was relatively small, Broman (1997) was able to employ a branch-and-bound procedure to obtain the optimal model according to each of the criteria (43). By good fortune, these three rules each selected the same 8-term model,

$$y_{ij} = \mu + \alpha s_j + \beta_2 x_{i2} + \beta_5 x_{i5} + \beta_9 x_{i9} + \beta_{13} x_{i,13} + \beta_{17} x_{i,17} + \delta_5 s_j x_{i5} + \epsilon_{ij}, \tag{44}$$

which includes the main effect for sex, five genotype main effects (occurring at markers 2, 5, 9, 13, and 17), and one sex $\times$ genotype interaction (at marker 5). To make a comparison with the MDL selection rules derived in Section 4.1.1, we again performed an exhaustive search for AIC, BIC, $gMDL$ and $nMDL$. As noted above, there are a number of McMC schemes that can be applied to find promising models based on $iMDL$ and SIC. We chose the so-called focused sampler of Wong, Hansen, Kohn and Smith (1998).[14] In Figure 5 we overlay these criteria, plotting the minimum of each as a function of the model dimension k. For easy comparison, we have mapped each curve to the interval $[0, 1]$. As noted by Broman (1997), BIC and

[13] This argument is meant as a heuristic; for the precise derivation of (43), the interested reader is referred to Broman (1997).

[14] The specific sampler is somewhat unimportant for the purpose of this paper. Any one of a number of schemes could be used to accomplish the same end.

hence AIC chose larger models that were primarily supersets of (44) involving 9 and 13 terms, respectively. Our two forms of mixture MDL, $gMDL$ and $iMDL$, and the Normalized Maximized Likelihood criterion, $nMDL$, were each in agreement with Broman's BIC_η, selecting model (44). Using the device introduced in the previous section (see Figure 4), we find that the equivalent penalty imposed by $gMDL$ was 7.4, which corresponds to an $\eta = 7.4/\log n = 7.4/\log 132 = 1.5$. For $nMDL$ the story was about the same with an equivalent penalty of 7.0 (or an η of 1.4). Finally, $iMDL$ had a penalty of 6.4 for an η of 1.3. These findings are satisfying in that our automatic procedures produced the same results as selection rules that have been optimized for the task of identifying non-spurious genetic markers from backcross experiments. Somewhat disappointingly, strict minimization of SIC identifies a model with 12 variables (and an equivalent penalty of 1.6, less than half of BIC's $\log 132 = 4.9$). From Figure 5, however, we see that the SIC curve is extremely flat in the neighborhood of its optimum, implying that an 11-term model provides virtually the same quality of fit. For $k = 11$, SIC selects a model that is a subset of that chosen according to AIC, but contains all of the terms in the model identified by BIC.

To summarize, we have compared the performance of several forms of MDL to a special-purpose selection criterion (43). For the most part, our results are consistent with Broman (1997), identifying (44) as the best model. The only poor performer in this context was SIC which fell between the poorly performing criteria AIC and BIC.

The color of supermarket produce. Our second regression example involves model selection in the context of function estimation. In Figure 6 we present a number of *spectral reflectance curves* obtained from samples of common fruits and vegetables. In total, measurements were taken on samples from some 70 varieties of popular produce, our ultimate goal being the creation of a recognition system that could augment supermarket check-out systems. For example, in the upper lefthand panel, each curve represents the color of a lemon measured at a small spot on its surface. The intensity of light reflected by its skin is recorded as a function of wavelength, producing a single curve in Figure 6. Because of noise considerations, we have restricted our measurements to a subset of the visible spectrum between 400 and 800 nm, recording values in 5 nm intervals. To remove the effects of varying surface reflectivity and to account for the possibility that the intensity of the incident light may vary from measurement to measurement, each curve has been normalized (across wavelength) to have mean zero and variance 1.

To make sense of these curves, consider the sample of limes represented in the upper rightmost corner of Figure 6. Limes are green because chlorophyll in their skin absorbs light strongly in the region between 680 and 700 nm. The dip in this region is evident in each of the lime measurements. Similarly, several of the bananas in our sample must have been slightly green because a few of the corresponding curves also drop in this region. In general, plant pigments absorb light in broad, overlapping bands and hence we expect our reflectance curves to be smooth functions of wavelength. The underlying chemistry manifests itself by varying the coarse features of each measurement. Finally, as should be apparent from Figure 6, our experimental setup allowed us to capture these curves with very little noise.

In this section, our goal is to derive a compact representation of these curves to be used for recognition purposes (see also, Furby, Kiiveri and Campbell, 1990). Dimension reduction is accomplished by simple projections onto an adaptively determined space of functions. Suppose we observe each curve at n distinct wavelengths $x_1, \ldots, x_n$. Then, consider the candidate basis functions of the form

$$B_i(x) = K(x, x_i) \quad \text{for } i = 1, \ldots, n\,,$$

where $K(\cdot, \cdot)$ is some specified *kernel* function. There are a number of choices for K, most falling into the class of so-called *radial basis functions* often used in neural networks (Hertz, Krough and Palmer, 1991). We choose instead to use the kernels that appear in the construction of smoothing splines (Wahba, 1990 and

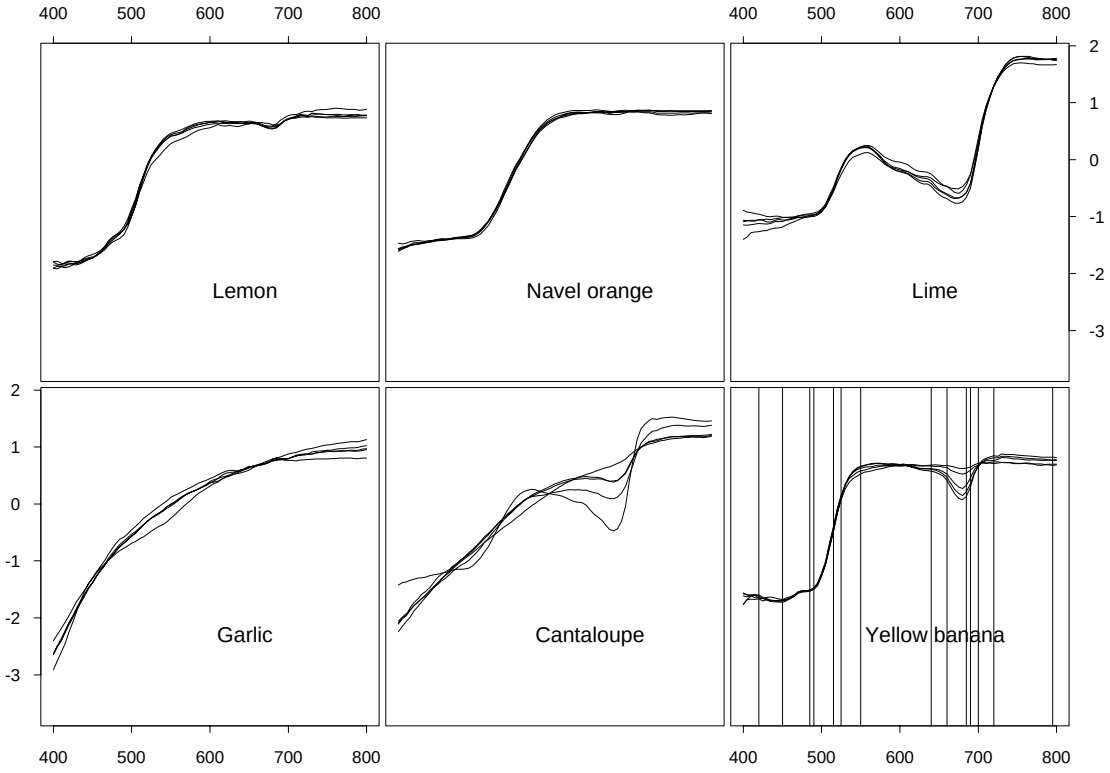

Figure 7: Spectral reflectance curves collected from 6 varieties of supermarket produce. In each panel, we plot 5 representative curves. Knot locations selected by $gMDL$ and BIC are marked by vertical lines in the lower right panel.

Wong et al., 1997). Then, having settled on a basis, we search for an approximation of the form

$$f(x) \approx \alpha_0 + \alpha_1 x + \sum_{i:\gamma_i=1} \beta_i B_i(x), \qquad x \in [400, 800] \tag{45}$$

where f is the true reflectance measurement taken from a sample of fruit and $\gamma \in \{0,1\}^n$ again indexes the candidate basis functions. Variable selection in (45) with B_i defined through smoothing spline kernels is equivalent to choosing knot locations in a natural spline space (Schumaker, 1981). Notice that in this case we always include a constant and linear term in our fits. (Because of our normalization, we do not need the constant term, but we include it in the equation above for completeness). In this context, Luo and Wahba (1997) employ a stepwise greedy algorithm to identify a model, while Wong et al. (1997) make use of the focused sampler after constructing a computationally feasible prior on γ. Finally, recall that a traditional smoothing spline estimate would fix $\gamma = (1, \ldots, 1)$ and perform a penalized fit (Wahba, 1990). See Hansen and Kooperberg (1998) for a general discussion of knot location strategies.

As mentioned above, the data presented in Figure 6 was collected as part of a larger project to create a classifier for recognizing supermarket produce based solely on its color. While we ultimately applied a variant of penalized discriminant analysis (Hastie, Buja and Tibshirani, 1995), a reasonably accurate scheme

involves dimension reduction (45) followed by simple linear discriminant analysis (LDA) on the coefficients β_i. Therefore, we adapted the MDL criteria introduced previously to handle multiple responses (curves). Our search for promising indices γ now represents identifying a single spline space (45) into which each curve is projected, producing inputs (coefficients) for a classification scheme like LDA. Given our extension of the MDL procedures to multiple responses, it is also possible to simply "plug in" each of these schemes to the flexible discriminant analysis technique of Hastie, Tibshirani and Buja (1994). The expansion (45), with its curve-by-curve projection into a fixed linear (although adaptively selected) space can be applied directly in this algorithm.

For our present purposes, we have roughly 30 curves for each variety listed in Figure 6 for a total of 176 response vectors. Because of the size of the problem, the best BIC and $gMDL$ models were computed using the focused sampler of Wong et al. (1997). We restricted our attention to these two forms purely on the basis of computational burden. The iterations (66) required by $iMDL$ are prohibitive given our current implementation of the algorithm. It is of course possible to take short-cuts with greedy, deterministic searches as proposed by Rissanen (1989). However, to simplify our presentation, we restrict our attention to only these two forms. In each case, 10,000 iterations of the sampler were used to identify the best expansion (45). To simplify our exposition even further, we were pleased to find that BIC and $gMDL$ agreed on the number of knots, and hence their placement as both select the minimal RSS model among candidates of the same dimension. In Figure 7 we highlight the locations of the selected knots, or rather the points x_i that correspond to kernel functions $B_i(\cdot) = K(\cdot, x_i)$ in the approximation (45). The higher density of knots in the neighborhood of 700 nm is expected. Because of chlorophyll's absorption properties, reflectance curves collected from green plants often exhibit a sharp rise in this region known as the *red edge*.

Based on these selected knot locations, we now project each curve into the linear space defined in (45). In the next section, the coefficients from these projections will be applied to an MDL-like clustering scheme.

4.2 Clustering Analysis

In this section, we apply a close cousin of MDL introduced by Wallace and Boulton (1968) and refined by Wallace and Freeman (1987). Originally designed for cluster analysis, their principle of Minimum Message Length (MML) also appeals to a notion of code length to strike a balance between model complexity and fidelity to the data. Under this framework, a two-part message is constructed, analogous to the two-stage coding scheme mentioned in Sections 2 and 3. For cluster analysis, a mixture of parametric models is proposed, so that the first part of the MML message consists of

- the number of clusters or components;
- the number of data points belonging to each cluster;
- the parameters needed to specify each model; and
- the cluster membership for each data point.

In the second part of the message, the data are encoded using the distribution of the specified model exactly as we described in Sections 2 and 3. As with MDL, the best MML model is the one with the shortest message length. In the words of Wallace and Boulton (1968), "a classification is regarded as a method of economical statistical encoding of the available attribute information."

When possible, MML will attempt to divide the data into homogeneous groups (implying that the model for each component captures the structure in the data), while penalizing the overall complexity or, rather, the total number of components. For the moment, the only practical difference between two-stage MDL and MML has to do with the precise encoding of the selected model. As these details are somewhat technical, the interested reader is referred to Baxter and Oliver (1995). Observe, however, that the restriction to two-part

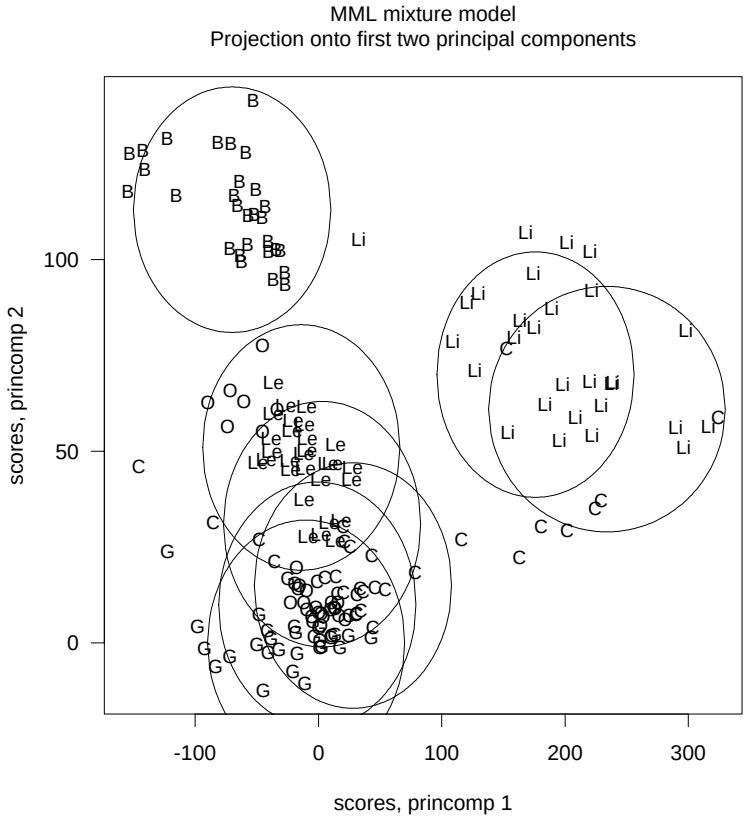

Figure 8: Mixture modeling via MML. SNOB finds 10 clusters for the projected reflectance curves. The ovals are contours of constant probability for the clusters that exhibit significant variation in the first two principal component directions. The symbols denote B = Banana, Li = Lime, Le = Lemon, C = Cantaloupe, O = Orange, and G = Garlic.

messages limits MML from taking advantage of other, more elaborate, coding schemes that still give rise to statistically-sound selection schemes.

To illustrate MML or the practical application of MDL to cluster analysis, we consider the produce data from the previous section. Recall that each spectral reflectance curve was projected onto a spline space (45) with the 14 knot locations specified in Figure 7. When combined with the linear term in (45) we obtain 15 estimated coefficients for each of our 176 curves. To this dataset we applied MML cluster analysis using SNOB, a public-domain Fortran program developed by Wallace's group at Monash University in Melbourne, Australia. The SNOB program and a number of relevant documents can be found through David Dowe's Web site `http://www.cs.monash.edu.au/~dld`. Wallace and Dowe (1994) describe the mixture modeling framework on which SNOB is based.

When clustering Gaussian data, each component of the mixture has a multivariate normal distribution with a diagonal covariance matrix. At present, SNOB assumes that all intra-class correlations are zero. Following a suggestion in the documentation, we orthogonalized the entire data set via a principal components decomposition. In Figure 8, have plotted the scores corresponding to the first two components, labeling points according to the class of each fruit. Clear divisions can be seen between, say, the limes and bananas. The

cantaloupe measurements stretch across a broad area at the bottom of this plot, an indication that it will be difficult to separate this class from the others. This is perhaps not surprising given the different colors that a cantaloupe can exhibit. The 10-cluster SNOB model is superimposed by projecting each Gaussian density in the mixture onto the space of the first two-dimensional principal components. Again, each component in this mixture is a Gaussian with diagonal variance-covariance matrix. In some cases, the SNOB clusters capture isolated groups of fruits (the bananas, lemons and limes, for example), while in other cases the color appears in too many different varieties.

4.3 Time Series Models

Our final application of MDL is to time series analysis. We emphasize predictive MDL which is especially natural in this setting. Our benchmarks will be AIC and BIC. In this context, determining the orders of an autoregressive-moving average (ARMA) process is a common model selection problem. Throughout this section we will focus on Gaussian ARMA(p,q) models, specified by the equation

$$x_t = \phi_1 x_{t-1} + \ldots + \phi_p x_{t-p} + Z_t + \theta_1 Z_{t-1} \ldots + \theta_q Z_{t-q}, \tag{46}$$

where the variables Z_t are iid Gaussian with mean 0 and variance σ^2. As is customary, we assume that the polynomials

$$1 - \phi_1 z - \ldots - \phi_p z^p = 0 \qquad \text{and} \qquad 1 - \theta_1 z - \ldots - \theta_q z^q = 0$$

have no roots in $|z| < 1$, so that equation (46) describes a stationary, second-order Gaussian process.

Given parameter values $\phi = (\phi_1, \ldots, \phi_p)$ and $\theta = (\theta_1, \ldots, \theta_q)$, and a series $x_1, \ldots, x_t$, it is straightforward to make predictions from (46) to times $t+1, t+2, \ldots$ conditional on the first t data points. For example, following Brockwell and Davis (1991, pp. 256), x_{t+1} has a Gaussian distribution with mean $\hat{x}_{t+1}$ and variance $\sigma^2 r_t$ which are calculable from the recursive formulae:

$$\begin{cases} \hat{x}_{t+1} &= \sum_{i=1}^{t} \theta_{it}(x_{t+1-i} - \hat{x}_{t+1-i}), & 1 \le t < \max(p,q) \\ \hat{x}_{t+1} &= \phi_1 x_t + \ldots + \phi_p x_{t+1-p} + \sum_{i=1}^{q} \theta_{it}(x_{t+1-i} - \hat{x}_{t+1-i}), & t \ge \max(p,q) \end{cases} \tag{47}$$

The extra parameters θ_{it} and r_t can be obtained recursively by applying the so-called innovation algorithm (Brockwell and Davis, Prop. 5.2.2., 1991) to the covariance function of the ARMA process.

We now turn to defining two forms of MDL in this context. For ease of notation, we will collect the parameters ϕ, θ and σ^2 into a single vector β. To emphasize the dependence of $\hat{x}_{t+1}$ and r_t on β, we write

$$\hat{x}_{t+1}(\beta) \quad \text{and} \quad r_t(\beta).$$

Hence the predictive density of x_{t+1} conditional on $x_1, \ldots, x_t$ is given by

$$q_t(x_{t+1}|\beta) = \left(2\pi r_t \sigma^2\right)^{-\frac{1}{2}} \exp\left(-\frac{1}{2r_t\sigma^2}(x_{t+1} - \hat{x}_{t+1})^2\right),$$

and the likelihood for β based on $x_1, \ldots, x_n$ is simply

$$q(\beta) = \prod_{t}^{n} q_t(x_{t+1}|\beta). \tag{48}$$

Letting $\hat{\beta}_n$ denote the MLE in this context, two stage MDL takes on the now familiar form of BIC

$$-\log q(\hat{\beta}_n) + \frac{p+q+1}{2}\log n.$$

The consistency proof of the two-stage MDL or BIC follows from Hannan and Quinn (1979) for AR models and from Gerencsér (1987) for general ARMA processes. As explained earlier, the complexity penalty $\log n/2$ comes from coding the parameter values at the estimation rate $1/\sqrt{n}$. When an AR model is not stable, Huang (1990) shows that this complexity penalty should be adjusted to the new estimation rate. For example, this leads to a complexity term $\log n$ for the explosive case where the estimation rate is $1/n$.

When modeling time series data, the predictive form of MDL is perhaps the most natural. Expressing the likelihood predictively, we arrive at the criterion

$$PMDL(p,q) = -\sum_{t=1}^{n} \log q_t(x_{t+1}|\hat{\beta}_t). \tag{49}$$

A closely related quantity for assessing the orders in ARMA models is the so-called accumulated prediction error (APE)

$$APE(p,q) = \sum_{t}^{n} (x_{t+1} - \hat{x}_{t+1})^2,$$

although APE was used long before the MDL principle. The computational cost of $PMDL$ can be enormous for general ARMA models since the parameter estimate $\hat{\beta}_t$ in (49) must be updated for each new observation. Hannan and Rissanen (1982) and Lai and Lee (1997) have proposed methods for reducing this cost. Consistency proofs for $PMDL$ order selection can be found for AR models in Hannan, McDougall, and Poskitt (1988) and Hemerly and Davis (1989a, 1989b), and for general ARMA models in Gerencsér (1987).

While deriving a mixture form of MDL appears possible by appealing to the state-space approach to ARMA processes (cf. Carlin, Polson, and Stoffer, 1992), selecting (computationally feasible) priors remains an active research area in its own right. In the next example, we apply AIC, BIC and $PMDL$ to the actual values (differenced) of the return series studied in Section 2.

Example 3 (continued) In the lefthand panel of Figure 2, we presented first differences of the daily return series. While our interest at that point was on compressing the string of up's and downs's, we now focus on the series itself. To ease the computational burden of $PMDL$, we choose to only update the parameter estimates every 100 days. We also restrict our attention to the first 6100 data points, intentionally stopping short of the spike induced by the stock market crash in 1987. Using the time series tools in S-PLUS, we fit our parameter estimates and recursively evaluated the likelihood (48) conditioned on the first 100 days. The standard analysis tools in S-PLUS allowed for a quick order determination via AIC and BIC. These criteria indicated that a simple MA(1) was in order. We then considered models where p and q varied (independently) over the range 0 to 5, and found that $PMDL$ also favors a MA(1) model. This result agrees with our initial work on the up-and-down series from Section 2. Undoubtedly, the (twice-differenced) DJIA series is much more complex than a simple ARMA process, but our goal here is to illustrate the application of MDL and not dabble in the stock market. □

5 Theoretical Results on MDL

In Section 3, we mentioned that the validity of an MDL model selection criterion depends on properties of the underlying coding scheme or, more precisely, the resulting description lengths. In this section we formalize these ideas in the context of regular parametric families (model classes). We first derive pointwise and minimax lower bounds on the code length with which data strings can be encoded with the help of a

class of models. Coding schemes yielding description lengths that achieve these lower bounds are said to produce valid MDL model selection criteria. Next, we return to the hypothesis tests of Example 4 and verify that the two-stage, predictive and mixture forms of description length all achieve these lower bounds. It has been shown that under very general conditions, MDL model selection criteria are consistent when the data-generating model belongs to the class being considered (cf. Barron et al., 1998). We end this section by illustrating why this is the case using the same simple framework of Example 4. For a more thorough treatment of the theoretical justifications of MDL, the interested reader is referred to the recent review article by Barron et al. (1998).

5.1 Rissanen's Pointwise Lower Bound

Given a parametric family or model class

$$\mathcal{M} = \{f_\theta(x^n) : \theta \in \Theta \subset \mathbb{R}^k\},$$

let $E_\theta\{\cdot\}$ denote the expectation with respect to a random variable (data string) X^n having density f_θ. (In contrast to previous sections, we are now going to be more careful when referring to random variables X^n versus points $x^n \in \mathbb{R}^n$.) Using this notation, the differential entropy of f_θ defined in (5) becomes

$$H_\theta(X^n) = -E_\theta \log f_\theta(X^n).$$

For any density (or prefix code) $q(x^n)$, the *Kullback-Leibler divergence* between f_θ and q is given by

$$\begin{aligned} R_n(f_\theta, q) &= E_\theta \log \frac{f_\theta(X^n)}{q(X^n)} \\ &= E_\theta \Big\{ -\log q(X^n) - \big[-\log f_\theta(X^n)\big] \Big\}. \end{aligned} \tag{50}$$

$R_n(f_\theta, q)$ represents the expected extra nats needed to encode the data string X^n using q rather than the optimal scheme based on f_θ. In coding theory, R_n is called the *(expected) redundancy* of q.

Defining a valid description length for a data string based on models from the class $\mathcal{M}$ reduces to finding a density q that achieves the "smallest" redundancy possible for all members in $\mathcal{M}$. To make this concrete, we first derive a lower bound on redundancy in a well-defined global sense over the entire class $\mathcal{M}$, and then illustrate choices for q that achieve it. We begin with a pointwise result first derived in Rissanen (1986a).

Assume that a $\sqrt{n}$-rate estimator $\hat{\theta}(x^n)$ for θ exists and the distribution of $\hat{\theta}(X^n)$ has uniformly summable tail probabilities:

$$P_\theta\{\sqrt{n}\|\hat{\theta}(X^n) - \theta\| \geq \log n\} \leq \delta_n, \qquad \text{for all } \theta \text{ and } \sum_n \delta_n < \infty,$$

where $\|\theta\|$ denotes some norm in $\mathbb{R}^k$. Then, for any density q, Rissanen (1986a) finds that

$$\liminf_{n\to\infty} \frac{E_\theta \log[\, f_\theta(X^n)/q(X^n)\,]}{(k/2)\log n} \;\geq\; 1, \tag{51}$$

for all $\theta \in \Theta$, except on a set of θ with a Lebesgue measure zero. This exceptional set depends on q and k. Viewing $-\log q(X^n)$ as the code length of an idealized prefix code, then (51) implies that without knowing the true distribution f_θ, we generally need at least $k \log n/2$ more bits to encode X^n, no matter what prefix code we use.

Shannon's source coding theorem (Section 2) quantifies the best expected code length when symbols from a known data-generating source are encoded with the density q (denoted by the distribution function

Q in Section 2). Rissanen's lower bound (51) extends this result to the case in which we only know that the "true" source belongs to some model class $\mathcal{M}$. In coding theory this is referred to as the problem of *universal coding*. Historically, the pointwise lower bound was the first to appear, which was followed by the minimax approach in the next section. The two approaches connect in Merhav and Feder (1995) where a lower bound on redundancy is obtained for abstract spaces. The pointwise lower bound (51) has been generalized to a special nonparametric class of models in density estimation by Rissanen, Speed, and Yu (1992) and their arguments should apply to other nonparametric settings.

5.2 Minimax Lower Bound

The bound (51) holds for almost every value of $\theta \in \Theta$, hence the term pointwise. We now turn to a minimax version of this result. We again focus on parametric classes. The interested reader is referred to Barron et al. (1998) for the minimax approach in MDL and nonparametric estimation.

First, we define the minimax redundancy to be

$$R_n^+ = \min_q \sup_{\theta \in \Theta} R_n(f_\theta, q). \tag{52}$$

This expression has a simple interpretation as the minimum over all coding schemes for X^n of the worst case redundancy over all parameter values θ. Next, consider a *prior* distribution $w(\theta)$ on the parameter space Θ and define the *Bayes redundancy* associated with a density q relative to w as

$$R_n^*(q, w) = \int_\Theta R_n(f_\theta, q) w(d\theta). \tag{53}$$

The *minimal Bayes redundancy* for a given w is given by

$$R_n(w) = \min_q R_n^*(q, w), \tag{54}$$

which is achieved by the *mixture* distribution

$$m^w(x^n) = \int_\Theta f_\theta(x^n) w(d\theta). \tag{55}$$

To see this, write

$$R_n^*(q, w) - R_n^*(m^w, w) = \int_{\mathcal{X}^n} \log \frac{m^w(x^n)}{q(x^n)} m^w(dx^n) \geq 0,$$

where the last relation holds from Jensen's inequality. Evaluating (54) at m^w yields

$$\begin{aligned} R_n(w) &= R_n^*(m^w, w) \\ &= \int_\Theta \int_{\mathcal{X}^n} \log \frac{f_\theta(x^n)}{m^w(x^n)} f_\theta(dx^n)\ w(d\theta) \end{aligned}$$

With a slight abuse of notation, if we let Θ also denote the random variable induced by the prior w, then the last expression above is known as the mutual information $I_w(\Theta; X^n)$ between Θ and the random variable $X^n = X_1, \ldots, X_n$ (Cover and Thomas, 1991). Therefore, we have established that

$$R_n(w) = I_w(\Theta; X^n). \tag{56}$$

The quantity I_w measures the average amount of information contained in the data X^n about the parameter Θ and has been used to measure information in a statistical context by Lindley as early as 1956 (cf. Lindley, 1956).

Let R_n^- denote the worst case minimal Bayes redundancy among all priors w:

$$R_n^- = \sup_w R_n(w). \tag{57}$$

This quantity also carries with it an information-theoretic interpretation. Here, R_n^- is referred to as the *channel capacity*, $C(\Theta; X^n)$. Following Cover and Thomas (1991), we envision sending a *message* consisting of a value of θ through a noisy channel represented by the conditional probability of X^n given θ. The receiver then attempts to reconstruct the message θ from X^n, or rather estimates θ from X^n. Assuming θ is to be sampled from a distribution $w(\theta)$, the channel capacity represents the maximal message rate that the noisy channel allows. The capacity-achieving distribution "spaces" the input values of θ, countering the channel noise and aiding message recovery (see Cover and Thomas, 1991).

Now, observe that the channel capacity $C(\Theta; X^n)$, bounds the minimax redundancy R_n^+ (52) from below:

$$\begin{aligned}
R_n^+ &= \min_q \sup_{\theta\in\Theta} R_n(f_\theta, q) \\
&\geq \sup_w \min_q \int_\Theta R_n(f_\theta, q) w(d\theta) \\
&= \sup_w \min_q R_n^*(q, w) \qquad (58) \\
&= \sup_w R_n(w) \qquad (59) \\
&\equiv C(\Theta; X^n),
\end{aligned}$$

where the equalities (58) and (59) are simply the definitions of the Bayes redundancy (53) and the minimal Bayes redundancy (57), respectively.

Haussler (1997) demonstrates that in fact the minimax redundancy (52) is equal to the channel capacity:

$$R_n^+ = C(\Theta; X^n) = R_n^-. \tag{60}$$

According to this result, if we can calculate the capacity of the channel defined by the pair w and f_θ, then we can get the minimax redundancy immediately. This statement was first proved by Gallager (1976), although the minimax result of this type for general loss functions was known prior to this point (cf. Le Cam, 1986). See also Davisson (1973), Davisson and Leon-Garcia (1980) and Csiszár (1990).

To be useful, this equivalence requires us to compute the channel capacity for a pair w and f_θ. Unfortunately, this can be a daunting calculation. When both the prior and density function are smooth, however, a familiar expansion can be employed to derive a reasonable approximation. Let $I(\theta)$ denote the Fisher information matrix defined by

$$I_{i,j}(\theta) = E\left[\frac{\partial}{\partial\theta_i}\log f(X|\theta)\frac{\partial}{\partial\theta_j}\log f(X|\theta)\right] \quad \text{for all } i,j = 1,\ldots,k.$$

Assume the observation sequence $X^n = X_1,\ldots,X_n$ are iid (or *memoryless* in the parlance of information theory) from some distribution f_θ in the class $\mathcal{M}$. Under regularity conditions on the prior w and the model class $\mathcal{M}$, Clarke and Barron (1990) derived the following expansion in the general k-dimensional case (see Ibragimov and Has'minsky, 1973, for the 1-dimensional case). Let K be a compact subset in the interior of Θ. Then, given a positive, continuous prior density w supported on K, the expected redundancy (51)

evaluated at the mixture distribution m^w (55) can be expanded as

$$R_n(f_\theta, m^w) = \frac{k}{2}\log\frac{n}{2\pi e} + \log\frac{\sqrt{\det I(\theta)}}{w(\theta)} + o(1),$$

where the $o(1)$ term is uniformly small on compact subsets interior to K. Averaging with respect to w yields an expansion for the minimal Bayes redundancy, or mutual information, (56)

$$\begin{aligned} R_n(w) &= I_w(\Theta; X^n) \\ &= \frac{k}{2}\log\frac{n}{2\pi e} + \int_K w(\theta)\log\frac{\sqrt{\det I(\theta)}}{w(\theta)}\,d\theta + o(1). \end{aligned}$$

The middle term is maximized by *Jeffreys' prior* (when this prior is well-defined):

$$w^*(\theta) = \frac{\sqrt{\det I(\theta)}}{\int_K \sqrt{\det I(\theta)}\,d\theta},$$

Hence the minimax redundancy satisfies

$$R_n^+ = \min_q \sup_{\theta\in\Theta} R_n(f_\theta, q) = \frac{k}{2}\log\frac{n}{2\pi e} + \log\int_K \sqrt{\det I(\theta)}\,d\theta + o(1). \tag{61}$$

Recalling the equivalence (60) and the channel capacity interpretation of the worst case minimal Bayes redundancy, Jeffreys' prior is now seen to be the *capacity-achieving* distribution for the channel defined by the pair w and $f_\theta(x^n)$. Intuitively, sampling a message θ according to Jeffreys' prior will result in channel inputs that are well separated in the sense that the probability of correctly reconstructing the message from X^n is high.

The leading term in (61) is the same $\frac{k}{2}\log n$ as in Rissanen's pointwise lower bound (51). Any code that achieves this leading term (to first order) on expected redundancy over a model class qualifies as a code to be used as the description length in the MDL selection for a model (Barron et al., 1998, address qualifying coding schemes based on the constant term). Such codes fairly represent all the members in the model class (in the minimax sense) without the knowledge of exactly which distribution generated our data string.

To gain perspective, we now contrast the analysis of the Kullback-Leibler divergence $R_n(f_\theta, q)$ defined in (51) that is carried out for the derivation of AIC with the analysis presented above. For AIC, we replace the distribution q with $f_{\hat\theta_n}$, where $\hat\theta_n$ is the maximum likelihood estimator of θ.[15] Under standard assumptions, the estimate $\hat\theta_n$ converges to θ in such a way that $R_n(f_\theta, f_{\hat\theta_n})$ has a negative $\frac{1}{2}\chi^2_k$ limiting distribution. Therefore, the Kullback-Liebler divergence $R_n(f_\theta, f_{\hat\theta_n})$ has a limiting mean of $-\frac{k}{2}$. This limit accounts for half of AIC's bias correction, the half associated with Kullback-Leibler divergence from f_θ due to parameter estimation, see Sakamoto, Ishiguro and Kitagawa (1985, p. 54) or Findley (1999). The minimax calculation in (61) is focussed on a q which is a joint density of x^n and determined by the set Θ. Moreover, it is shown in Rissanen (1996) that the minimax redundancy is achieved asymptotically by the joint density (when it exists) corresponding to the normalized maximum likelihood (NML) code. That is, $f_{\hat\theta_n}(x^n)/C_n$ where C_n is the normalization constant required to make $f_{\hat\theta_n}(x^n)$ into a joint density or a code. The $-\frac{k}{2}$ term from the unnormalized maximum likelihood estimator as in the AIC case appears as $\frac{k}{2}\log\frac{1}{e}$ and the rest of the terms in (61) give the asymptotic expansion of C_n (cf. Barron et al, 1998). Hence, MDL criteria that achieve minimax redundancy can be viewed as more conservative criteria that AIC from the perspective of Kullback-Leibler divergence.

[15] Note that $f_{\hat\theta_n}$ is an estimator of the joint density of x^n, but is not a joint distribution. Therefore, it cannot be used to generate a code.

For more general parameter spaces, Merhav and Feder (1995) prove that the capacity of the induced channel is a lower bound on the redundancy that holds simultaneously for all sources in the class except for a subset of points whose probability, under the capacity-achieving probability measure, vanishes as n tends to infinity. Because of the relationship between channel capacity and minimax redundancy, this means that the minimax redundancy is a lower bound on the redundancy for "most" choices of the parameter θ, hence generalizing Risssanen's lower bound.

For the case when the source is memoryless, that is, when the observations are conditionally independent given the true parameter θ, and have a common distribution f_θ, $\theta \in \Theta$, Haussler and Opper (1997) obtain upper and lower bounds on the mutual information in terms of the relative entropy and Hellinger distance. Using these bounds and the relation between the minimax redundancy and channel capacity, asymptotic values for minimax redundancy can be obtained for abstract parameter spaces.

5.3 Achievability of Lower Bounds by Different Forms of Description Length

In regular parametric families (model classes), the forms of description length introduced in Section 3 all achieve the $\frac{k}{2}\log n$ asymptotic lower bounds on redundancy, both in the pointwise and minimax senses. They therefore qualify as description lengths (to first order) to be used in MDL model selection. We illustrate this through our running Example 4 from Section 2.3. Our notation for a random data string will now revert to that from Section 4, so that x^n represents a random sequence $x_1, \ldots, x_n$.

Example 4 (continued) Two-stage MDL. Trivially, because $\mathcal{M}_0$ consists of a single distribution, the expected redundancy of L_0 given in (4) is zero. Now, for $\theta \neq 0$, give above (11)

$$-\log f_\theta(x^n) = \frac{n}{2}\log(2\pi) + \frac{1}{2}\sum_{t=1}^{n}(x_t - \theta)^2.$$

Therefore, the expected redundancy between f_θ and the code length function L_1 (11) is given by

$$\begin{aligned} E_\theta\big\{\log f_\theta(x^n) - L_1(x^n)\big\} &= \frac{n}{2}E_\theta\{\bar{x}_n - \theta\}^2 + \frac{1}{2}\log n \\ &= \frac{1}{2} + \frac{1}{2}\log n, \end{aligned}$$

which for $k = 1$ achieves the pointwise lower bound (51).

Heuristically, for a general k-dimensional regular parametric family, it is well-known that the quantity

$$-\log \frac{f_{\hat{\theta}}(x^n)}{f_\theta(x^n)}$$

has an asymptotic χ^2_k distribution hence its expected value should be $\frac{k}{2}$, which is of smaller order than $\frac{k}{2}\log n$. Thus the two-stage description length achieves the lower bound.

Mixture MDL. As with the two-stage scheme, the redundancy of L_0 is zero because $\mathcal{M}_0$ consists of a single model. Now, starting with expression (15) we can calculate the expected redundancy for L_1

$$\begin{aligned} &\frac{1}{2}\log(1+n\tau) + \frac{1}{2}\frac{n}{1+1/(n\tau)}E_\theta\,\bar{x}^2 - \sum_t \theta E_\theta\, x_t + \frac{1}{2}n\theta^2 \\ &\quad = \frac{1}{2}\log(1+n\tau) + \frac{1}{2}\frac{n}{1+1/(n\tau)}(1/n + \theta^2) - n\theta^2/2 \\ &\quad = \frac{1}{2}\log n + O(1), \end{aligned}$$

which clearly achieves the pointwise lower bound (51). In addition, given any prior distribution w on Θ, we can construct a prefix code according to the mixture distribution m^w (55). The corresponding code length is

$$L(x^n) = -\log \int w(d\theta)\, f_\theta(x^n).$$

As mentioned above, under certain regularity conditions, Clarke and Barron (1990) showed that the redundancy of the mixture code has the following asymptotic expansion for a regular family of dimension k:

$$R_n(m^w, \theta) = \frac{k}{2} \log \frac{n}{2\pi e} + \frac{1}{2} \log \frac{\sqrt{\det I(\theta)}}{w(\theta)} + o(1)\,.$$

It follows that the mixture code achieves the minimax lower bound, and as we have mentioned earlier, Jeffreys' prior maximizes the constant term in the minimax redundancy (cf. Barron et al., 1998).

Predictive MDL. Using (22), it is easy to check that the redundancy

$$\begin{aligned} E_\theta(-\log q(x^n) + \log f_\theta(x^n)) &= \frac{1}{2}\sum_{t=1}^{n}(1 + 1/t) - n/2 \\ &= \frac{1}{2}\sum_{t=1}^{n} 1/t \\ &= \frac{1}{2}\log n + O(1). \end{aligned}$$

Thus it achieves the lower bound (51) and can be used as the description length for data based on model $\mathcal{M}_1$. As with the previous two forms, the expected redundancy of L_0 is zero.

For more general cases, Rissanen (1986b, Theorem 3) proved that the predictive code based on the maximum likelihood estimator achieves the pointwise redundancy lower bound under regularity conditions. □

5.4 Assessing MDL Model Selection Procedures in Terms of Consistency and Prediction Errors

Although MDL has a solid motivation from the viewpoint of noiseless compression of data, which itself has a close tie to statistical estimation, it is not clear a priori whether or not MDL will lead to model selection procedures that are sensible statistically. One criterion used in assessing model selection procedures is consistency when a finite-dimensional "true" model is assumed. That is, as the sample size gets large, a consistent procedure will pick the correct model class with probability approaching 1. The two-stage, predictive, and mixture forms of MDL are consistent in the regression case (cf. Speed and Yu, 1994). In general, different MDL forms are consistent under very weak conditions (cf. Barron et al, 1998). The predictive code takes the form of predictive least squares in time series and stochastic regression models. See Hemerly and Davis (1989) for time series models and Wei (1992) for general stochastic regression models and the consistency of the predictive form. We illustrate the consistency of MDL through the two-stage code in our running example.[16]

[16] Under the same finite dimensional "true" model assumption, as an alternative to the consistency assessment, Merhav (1989) and Merhav, Gutman and Ziv (1989) analyze model selection criteria by studying the best possible underfitting probability while exponentially restricting the overfitting probability.

Example 4 (continued) Recall that two-stage MDL or BIC will select $\mathcal{M}_0$ if $|\bar{x}_n| \leq \sqrt{\log n/n}$. When $\mathcal{M}_1$ is true, the probability of *underfitting* is

$$\begin{aligned} P(\mathcal{M}_0 \text{ is selected}) &= P_\theta(|\bar{x}_n| \leq \sqrt{\log n/n}) \\ &\approx P_\theta(N(0,1) \geq \theta\sqrt{n} - \sqrt{\log n}) \\ &\approx O(e^{-n\theta^2/2}). \end{aligned}$$

Similarly, when $\mathcal{M}_0$ is true, the probability of *overfitting* is

$$\begin{aligned} P(\mathcal{M}_1 \text{ is selected}) &= P_\theta(|\bar{x}_n| > \sqrt{\log n/n}) \\ &= P_\theta(|N(0,1)| > \sqrt{\log n}) \\ &\approx O(1/\sqrt{n}). \end{aligned}$$

Therefore, two-stage MDL yields a consistent model selection rule. □

In general, an exponential decay rate on the underfitting probability and an algebraic decay rate on the overfitting probability hold for the predictive and mixture MDL forms, and also for other regression models (cf. Speed and Yu, 1994). Consistency of MDL follows immediately. It also follows from and examination of the underfitting probability that for finite sample sizes, consistency is effected by the magnitude of θ^2 (or squared bias in general) relative to n, and not the absolute magnitude of θ^2. Speed and Yu (1994) also studied the behavior of MDL criteria in two prediction frameworks: prediction without refitting and prediction with refitting. In both cases, MDL (and BIC) turned out to be optimal if the true regression model is finite dimensional. AIC is not consistent, but the consequence in terms of prediction errors is not severe: the ratio of AIC 's prediction error and that of any form of MDL (or BIC) is bounded.

No model is true in practice, but the finite dimensional model assumption in regression does approximate the practical situation where the model bias has a "cliff" or a sharp drop at a certain sub-model class under consideration, or when the covariates can be divided into two groups of which one is very important and the other marginal and no important covariates are missing from consideration. When bias decays gradually and never hits zero, however, the consistency criterion does not make sense. In this case, prediction error provides insight into the performance of a selection rule. Shibata (1981) shows that AIC is optimal for these situations, at least in terms of one-step ahead prediction error. The simulation studies in Section 4 illustrate that by trading off between bias and variance it is possible to create examples in which BIC outperforms AIC and vice versa. A similar point was made in Speed and Yu (1994). When the covariates under consideration are misspecified or superfluous, Findley (1991) gives examples both in regression and time series models where the bigger model always gives a smaller prediction error thus suggesting AIC is better for these particular models. For exactly these reasons, we believe adaptive model selection criteria likc $gMDL$ are very useful.

6 Conclusion

In this article, we have reviewed the Principle of Minimum Description length and its various applications to statistical model selection. Through a number of simple examples, we have motivated the notion of code length as a measure for evaluating competing descriptions of data. This brings a rich information-theoretic interpretation to statistical modeling. Throughout this discussion, our emphasis has been on the

practical aspects of MDL. Toward that end, we developed in some detail MDL variable selection criteria for regression, perhaps the most widely applied modeling framework. As we have seen, the resulting procedures have connections with both frequentist and Bayesian methods. Two mixture forms of MDL, $iMDL$ and $gMDL$ exhibit a certain degree of adaptability, allowing them to perform like AIC at one extreme and BIC at the other. To illustrate the scope of the MDL framework, we have also discussed model selection in the context of curve estimation, cluster analysis and order selection in ARMA models.

Some care has gone into the treatment of so-called valid description lengths. This notion is important, as it justifies the use of a given coding scheme for comparing competing models. Any implementation of MDL depends on the establishment of a universal coding theorem, guaranteeing that the resulting selection rule has good theoretical properties, at least asymptotically. The two-stage, mixture, predictive and normalized maximized likelihood coding schemes all produce valid description lengths. Our understanding of the finite-sample performance of even these existing MDL criteria, will improve as they find greater application within the statistics community. To aid this endeavor, the MDL procedures discussed in this paper will be made available by the first author in the form of an S-PLUS library.

Inspired by algorithmic complexity theory, the descriptive modeling philosophy of MDL adds to other more traditional views of statistics. Within engineering, MDL is being applied to ever more exotic modeling situations, and there is no doubt that new forms of description length will continue to appear. MDL provides an objective umbrella under which rather disparate approaches to statistical modeling can co-exist and be compared. In crafting this discussion, we have tried to point out interesting open problems and areas needing statistical attention. At the top of this list is the incorporation of uncertainty measures into the MDL framework. The close ties with Bayesian statistics yields a number of natural suggestions in this direction, but nothing formal has been done in this regard. The practical application of MDL in nonparametric problems should also provide a rich area of research, as theoretical results in this direction are already quite promising (see, for example, Barron and Yang, 1998; and Yang, 1999).

7 Acknowledgements

The authors would like to thank Jianhua Huang for his help with a preliminary draft of this paper. The authors would also like to thank two anonymous referees, Ed George, Robert Kohn, Wim Sweldens, Martin Wells, Andrew Gelman, and John Chambers for helpful comments.

8 Appendix

We begin with the normal-inverse-gamma family of conjugate priors for the normal linear regression model (23). Setting $\tau = \sigma^2$, these densities are given by

$$w(\beta, \tau) \;\propto\; \tau^{\frac{-d+k+2}{2}} \exp\left[\frac{-(\beta-b)^t V^{-1}(\beta-b)+a}{2\tau}\right], \tag{62}$$

and depend on several hyperparameters: $a, d \in \mathbb{R}$, the vector $b \in \mathbb{R}^k$, and a $k \times k$ symmetric, positive definite matrix V. Valid ranges for these parameters include all values that make (62) a proper density. Under this class of priors, the mixture distribution (30) has the form

$$-\log m(y|X) \;=\; \frac{1}{2}\log|V| \;-\; \frac{1}{2}\log|V^*| \;-\; \frac{d}{2}\log a \;+\; \frac{d^*}{2}\log a^*, \tag{63}$$

ignoring terms that do not depend on our particular choice of model, where

$$d^* \;=\; d+n\,, \qquad V^* \;=\; (V^{-1}+X^tX)^{-1}\,, \qquad b^* \;=\; V^*(V^{-1}b+X^ty)\,,$$

and

$$a^* \;=\; a + y^t y + b^t V^{-1} b - (b^*)^t (V^*)^{-1} b^* \,.$$

The derivation of $m(y|X)$, the marginal or predictive distribution of y, is standard and can be found in O'Hagan (1994).

To implement this mixture form of MDL, we have to settle on values for the hyperparameters. In his original derivation, Rissanen (1989) considers normal-inverse-gamma priors with

$$d \;=\; 1\,, \quad V \;=\; c^{-1}\,\Sigma\,, \quad \text{and} \quad b \;=\; (0, \ldots, 0)\,. \tag{64}$$

After making these substitutions, we then want to minimize the expression (63) over the two hyperparameters a and c. First, a straightforward calculation gives us the closed-form expression $\hat{a} = R_c/n$. Substituting $\hat{a}$ for a, we arrive at the log-likelihood

$$-\log\, m(y|X, \hat{a}, c) \;=\; -\frac{1}{2}\log|c\Sigma^{-1}| \;+\; \frac{1}{2}\,\log\,\left|\, c\Sigma^{-1} + X^t X\,\right| \;+\; \frac{n}{2}\,\log\, R_c\,. \tag{65}$$

Surprisingly, we obtain this form no matter how we select d in our prior specification (64), so $d = 1$ is not a restrictive choice. This form, in fact, is equivalent to a mixture distribution computed under the so-called weak prior corresponding to $a = d = 0$; a choice of hyperparameters that assigns the improper prior $1/\tau$ to τ.

Unfortunately, optimizing over c presents us with a more difficult problem. After differentiating (31), we find that $\hat{c}$ must satisfy

$$\hat{c} = \frac{k R_{\hat{c}}}{R_{\hat{c}}\;\mathrm{trace}\left[\,\Sigma^{-1}\,(\,\hat{c}\,\Sigma^{-1} \,+\, X'X)^{-1}\,\right] \;+\; n\, y^t X\,\left(\,\hat{c}\,\Sigma^{-1} + X^t X\,\right)^{-1}\,\Sigma^{-1}\,\left(\,\hat{c}\,\Sigma^{-1} \,+\, X^t X\,\right)^{-1}\,X^t y}. \tag{66}$$

This expression can be be applied iteratively, with convergence typically requiring fewer than twenty steps, depending on the starting values. In deriving what we have called $iMDL$, Rissanen (1989, pp. 129) exhibits a slightly different relationship for the special case of $\Sigma = I_{k\times k}$. (The difference is presumably the result of transcription errors.) To obtain $gMDL$, we instead choose $\Sigma = (X^t X)^{-1}$, and we arrive at the expression for $\hat{c}$ given in (33) either by direct substitution in (66) or by minimizing (65).
